Welcome

This book is a web complement to MATH 80601A *Bayesian modelling*, a graduate course offered at HEC Montréal.

These notes are licensed under a Creative Commons Attribution-NonCommercial-ShareAlike 4.0 International License and were last compiled on Monday, October 02 2023.

The objective of the course is to provide a hands on introduction to Bayesian data analysis. The course will cover the formulation, evaluation and comparison of Bayesian models through examples and real-data applications.

1 Bayesics

The Bayesian paradigm is an inferential framework that is used widespread in data science. Numerical challenges that prevented its widespread adoption until the 90's, when the Markov chain Monte Carlo revolution allowed models estimation.

Bayesian inference, which builds on likelihood-based inference, offers a natural framework for prediction and for uncertainty quantification. The interpretation is more natural than that of classical (i.e., frequentist) paradigm, and it is more easy to generalized models to complex settings, notably through hierarchical constructions. The main source of controversy is the role of the prior distribution, which allows one to incorporate subject-matter expertise but leads to different inferences being drawn by different practitioners; this subjectivity is not to the taste of many and has been the subject of many controversies.

The Bayesian paradigm includes multiples notions that are not covered in undergraduate introductory courses. The purpose of this chapter is to introduce these concepts and put them in perspective; the reader is assumed to be familiar with basics of likelihood-based inference. We begin with a discussion of the notion of probability, then define priors, posterior distributions, marginal likelihood and posterior predictive distributions. We focus on the interpretation of posterior distributions and explain how to summarize the posterior, leading leading to definitions of high posterior density region, credible intervals, posterior mode for cases where we either have a (correlated) sample from the posterior, or else have access to the whole distribution. Several notions, including sequentiality, prior elicitation and estimation of the marginal likelihood, are mentioned in passing. A brief discussion of Bayesian hypothesis testing (and alternatives) is presented.

1.1 Probability and frequency

In classical (frequentist) parametric statistic, we treat observations \mathbf{Y} as realizations of a distribution whose parameters θ are unknown. All of the information about parameters is encoded by the likelihood function.

The interpretation of probability in the classical statistic is in terms of long run frequency, which is why we term this approach frequentist statistic. Think of a fair die: when we state that values $\{1, \dots, 6\}$ are equiprobable, we mean that repeatedly tossing the die

1 Bayesics

should result, in large sample, in each outcome being realized roughly $1/6$ of the time (the symmetry of the object also implies that each facet should be equally likely to lie face up). This interpretation also carries over to confidence intervals: a $(1 - \alpha)$ confidence interval either contains the true parameter value or it doesn't, so the probability level $(1 - \alpha)$ is only the long-run proportion of intervals created by the procedure that should contain the true fixed value, not the probability that a single interval contains the true value. This is counter-intuitive to most.

In practice, the true value of the parameter θ vector is unknown to the practitioner, thus uncertain: Bayesians would argue that we should treat the latter as a random quantity rather than a fixed constant. Since different people may have different knowledge about these potential values, the prior knowledge is a form of **subjective probability**. For example, if you play cards, one person may have recorded the previous cards that were played, whereas other may not. They thus assign different probability of certain cards being played. In Bayesian inference, we consider θ as random variables to reflect our lack of knowledge about potential values taken. Italian scientist Bruno de Finetti, who is famous for the claim “Probability does not exist”, stated in the preface of Finetti (1974):

Probabilistic reasoning — always to be understood as subjective — merely stems from our being uncertain about something. It makes no difference whether the uncertainty relates to an unforeseeable future, or to an unnoticed past, or to a past doubtfully reported or forgotten: it may even relate to something more or less knowable (by means of a computation, a logical deduction, etc.) but for which we are not willing or able to make the effort; and so on [...]. The only relevant thing is uncertainty — the extent of our knowledge and ignorance. The actual fact of whether or not the events considered are in some sense *determined*, or known by other people, and so on, is of no consequence.

On page 3, de Finetti continues (Finetti 1974)

only subjective probabilities exist — i.e., the degree of belief in the occurrence of an event attributed by a given person at a given instant and with a given set of information.

1.2 Posterior distribution

We consider a parametric model with parameters θ defined on $\Theta \subseteq \mathbb{R}^p$. In Bayesian learning, we adjoin to the likelihood $\mathcal{L}(\theta; \mathbf{y}) \equiv p(\mathbf{y} | \theta)$ a **prior** function $p(\theta)$ that reflects the prior knowledge about potential values taken by the p -dimensional parameter vector, before

1.2 Posterior distribution

observing the data \mathbf{y} . The prior makes θ random and the distribution of the parameter reflects our uncertainty about the true value of the model parameters.

In a Bayesian analysis, observations are random variables but inference is performed conditional on the observed sample values. By Bayes' theorem, our target is therefore the posterior density $p(\theta | \mathbf{y})$, defined as

$$\underbrace{p(\theta | \mathbf{y})}_{\text{posterior}} = \frac{\underbrace{p(\mathbf{y} | \theta)}_{\text{likelihood}} \times \underbrace{p(\theta)}_{\text{prior}}}{\underbrace{\int p(\mathbf{y} | \theta) p(\theta) d\theta}_{\text{marginal likelihood } p(\mathbf{y})}}. \quad (1.1)$$

The posterior $p(\theta | \mathbf{y})$ is proportional, as a function of θ , to the product of the likelihood and the prior function.

For the posterior to be **proper**, we need the product of the prior and the likelihood on the right hand side to be integrable as a function of θ over the parameter domain Θ . The integral in the denominator, termed marginal likelihood or prior predictive distribution and denoted $p(\mathbf{y}) = E_{\theta}\{p(\mathbf{y} | \theta)\}$. It represents the distribution of the data before data collection, the respective weights being governed by the prior probability of different parameters values. The denominator of Equation 1.1 is a normalizing constant, making the posterior density integrate to unity. The marginal likelihood plays a central role in Bayesian testing.

If θ is low dimensional, numerical integration such as quadrature methods can be used to compute the marginal likelihood.

To fix ideas, we consider next a simple one-parameter model where the marginal likelihood can be computed explicitly.

Example 1.1 (Binomial model with beta prior). Consider a binomial likelihood with probability of success $\theta \in [0, 1]$ and n trials, $Y \sim \text{Bin}(n, \theta)$. If we take a beta prior, $\theta \sim \text{Be}(\alpha, \beta)$ and observe y successes, the posterior is

$$\begin{aligned} p(\theta | y = y) &\propto \binom{n}{y} \theta^y (1 - \theta)^{n-y} \frac{\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)} \theta^{\alpha-1} (1 - \theta)^{\beta-1} \\ &\propto \theta^{y+\alpha-1} (1 - \theta)^{n-y+\beta-1} \end{aligned}$$

and is

$$\int_0^1 \theta^{y+\alpha-1} (1 - \theta)^{n-y+\beta-1} d\theta = \frac{\Gamma(y + \alpha) \Gamma(n - y + \beta)}{\Gamma(n + \alpha + \beta)},$$

1 Bayesics

a Beta function. Since we need only to keep track of the terms that are function of the parameter θ , we could recognize directly that the posterior distribution is $\text{Be}(y + \alpha, n - y + \beta)$ and deduce the normalizing constant from there.

If $Y \sim \text{Bin}(n, \theta)$, the expected number of success is $n\theta$ and the expected number of failures $n(1 - \theta)$ and so the likelihood contribution, relative to the prior, will dominate as the sample size n grows.

Another way to see this is to track moments (expectation, variance, etc.) The Beta distribution, whose density is $f(x; \alpha, \beta) \propto x^{\alpha-1}(1-x)^{\beta-1}$, has expectation $\alpha/(\alpha + \beta)$ and variance $\alpha\beta/\{(\alpha + \beta)^2(\alpha + \beta + 1)\}$. The posterior mean is

$$\mathbb{E}(\theta | y) = w \frac{y}{n} + (1 - w) \frac{\alpha}{\alpha + \beta}, \quad w = \frac{n}{n + \alpha + \beta},$$

a weighted average of the maximum likelihood estimator and the prior mean. We can think of the parameter α (respectively β) as representing the fixed prior number of success (resp. failures). The variance term is $O(n^{-1})$ and, as the sample size increases, the likelihood weight w dominates.

Figure 1.1 shows three different posterior distributions with different beta priors: the first prior, which favors values closer to $1/2$, leads to a more peaked posterior density, contrary to the second which is symmetric, but concentrated toward more extreme values near endpoints of the support. The rightmost panel is truncated: as such, the posterior is zero for any value of θ beyond $1/2$ and so the posterior mode may be close to the endpoint of the prior. The influence of such a prior will not necessarily vanish as sample size and should be avoided, unless there are compelling reasons for restricting the domain.

Remark (Proportionality). Any term appearing in the likelihood times prior function that does not depend on parameters can be omitted since they will be absorbed by the normalizing constant. This makes it useful to compute normalizing constants or likelihood ratios.

Remark. An alternative parametrization for the beta distribution sets $\alpha = \mu\kappa$, $\beta = (1 - \mu)\kappa$ for $\mu \in (0, 1)$ and $\kappa > 0$, so that the model is parametrized directly in terms of mean μ , with κ capturing the dispersion.

Remark. A density integrates to 1 over the range of possible outcomes, but there is no guarantee that the likelihood function, as a function of θ , integrates to one over the parameter domain Θ .

For example, the binomial likelihood with n trials and y successes satisfies

$$\int_0^1 \binom{n}{y} \theta^y (1 - \theta)^{n-y} d\theta = \frac{1}{n + 1}.$$

Figure 1.1: Scaled binomial likelihood for six successes out of 14 trials, with Beta(3/2, 3/2) prior (left), Beta(1/4, 1/4) (middle) and truncated uniform on $[0, 1/2]$ (right), with the corresponding posterior distributions.

Moreover, the binomial distribution is discrete with support $0, \dots, n$, whereas the likelihood is continuous as a function of the probability of success, as evidenced by Figure 1.2

Proposition 1.1 (Sequentiality and Bayesian updating). *The likelihood is invariant to the order of the observations if they are independent. Thus, if we consider two blocks of observations \mathbf{y}_1 and \mathbf{y}_2*

$$p(\boldsymbol{\theta} \mid \mathbf{y}_1, \mathbf{y}_2) = p(\boldsymbol{\theta} \mid \mathbf{y}_1)p(\boldsymbol{\theta} \mid \mathbf{y}_2),$$

so it makes no difference if we treat data all at once or in blocks. More generally, for data exhibiting spatial or serial dependence, it makes sense to consider rather the conditional (sequential) decomposition

$$f(\mathbf{y}; \boldsymbol{\theta}) = f(\mathbf{y}_1; \boldsymbol{\theta})f(\mathbf{y}_2; \boldsymbol{\theta}, \mathbf{y}_1) \cdots f(\mathbf{y}_n; \boldsymbol{\theta}, \mathbf{y}_1, \dots, \mathbf{y}_{n-1})$$

where $f(\mathbf{y}_k; \mathbf{y}_1, \dots, \mathbf{y}_{k-1})$ denotes the conditional density function given observations $\mathbf{y}_1, \dots, \mathbf{y}_{k-1}$.

1 Bayesics

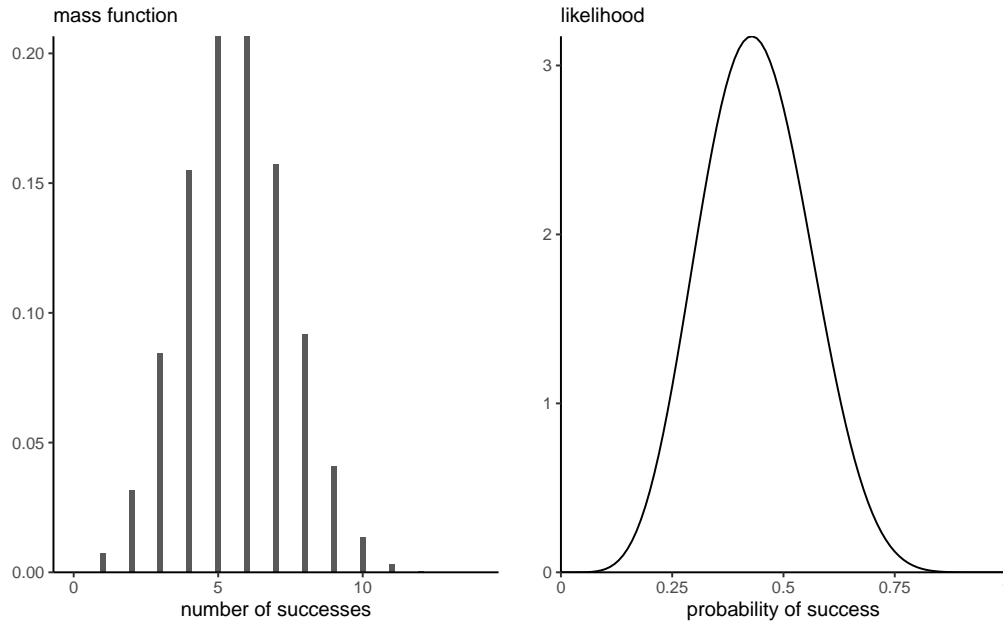

Figure 1.2: Binomial mass function (left) and scaled likelihood function (right).

By Bayes' rule, we can consider updating the posterior by adding terms to the likelihood, noting that

$$p(\boldsymbol{\theta} \mid \mathbf{y}_1, \mathbf{y}_2) \propto p(\mathbf{y}_2 \mid \mathbf{y}_1, \boldsymbol{\theta})p(\boldsymbol{\theta} \mid \mathbf{y}_1)$$

which amounts to treating the posterior $p(\boldsymbol{\theta} \mid \mathbf{y}_1)$ as a prior. If data are exchangeable, the order in which observations are collected and the order of the belief updating is irrelevant to the full posterior. Figure 1.3 shows how the posterior becomes gradually closer to the scaled likelihood as we increase the sample size, and the posterior mode moves towards the true value of the parameter (here 0.3).

Example 1.2. While we can calculate analytically the value of the normalizing constant for the beta-binomial model, we could also for arbitrary priors use numerical integration or Monte Carlo methods in the event the parameter vector $\boldsymbol{\theta}$ is low-dimensional.

While estimation of the normalizing constant is possible in simple models, the following highlights some challenges that are worth keeping in mind. In a model for discrete data (that is, assigning probability mass to a countable set of outcomes), the terms in the likelihood are probabilities and thus the likelihood becomes smaller as we gather more observations

1.2 Posterior distribution

Figure 1.3: Beta posterior and binomial likelihood with a uniform prior for increasing number of observations (from left to right) out of a total of 100 trials.

(since we multiply terms between zero or one). The marginal likelihood term becomes smaller and smaller, so its reciprocal is big and this can lead to arithmetic underflow.

```
y <- 6L # number of successes
n <- 14L # number of trials
alpha <- beta <- 1.5 # prior parameters
unnormalized_posterior <- function(theta){
  theta^(y+alpha-1) * (1-theta)^(n-y + beta - 1)
}
integrate(f = unnormalized_posterior,
          lower = 0,
          upper = 1)
#> 0.0000107 with absolute error < 1e-12
# Compare with known constant
beta(y + alpha, n - y + beta)
#> [1] 0.0000107
# Monte Carlo integration
mean(unnormalized_posterior(runif(1e5)))

```

1 Bayesics

When θ is high-dimensional, the marginal likelihood is intractable. This is one of the main challenges of Bayesian statistics and the popularity and applicability has grown drastically with the development and popularity of numerical algorithms, following the publication of Geman and Geman (1984) and Gelfand and Smith (1990). Markov chain Monte Carlo methods circumvent the calculation of the denominator by drawing approximate samples from the posterior.

1.3 Posterior predictive distribution

Prediction in the Bayesian paradigm is obtained by considering the *posterior predictive distribution*,

$$p(y_{\text{new}} | \mathbf{y}) = \int_{\Theta} p(y_{\text{new}} | \theta) p(\theta | \mathbf{y}) d\theta$$

Given draws from the posterior distribution, say θ_b ($b = 1, \dots, B$), we sample from each a new realization from the distribution appearing in the likelihood $p(y_{\text{new}} | \theta_b)$. This is different from the frequentist setting, which fixes the value of the parameter to some estimate $\hat{\theta}$; by contrast, the posterior predictive, here a beta-binomial distribution $\text{BetaBin}(n, \alpha + y, n - y + \beta)$, carries over the uncertainty so will typically be wider and overdispersed relative to the corresponding binomial model. This can be easily seen from the left-panel of Figure 1.4, which contrasts the binomial mass function evaluated at the maximum likelihood estimator $\hat{\theta} = 6/14$ with the posterior predictive.

```
npost <- 1e4L
# Sample draws from the posterior distribution
post_samp <- rbeta(n = npost, y + alpha, n - y + beta)
# For each draw, sample new observation
post_pred <- rbinom(n = npost, size = n, prob = post_samp)
```

Example 1.3 (Posterior predictive distribution of univariate Gaussian with known mean). Consider an n sample of independent and identically distributed Gaussian, $Y_i \sim \text{No}(0, \tau^{-1})$ ($i = 1, \dots, n$), where we assign a gamma prior on the precision $\tau \sim \text{Ga}(\alpha, \beta)$. The posterior is

$$p(\tau | \mathbf{y}) \propto \prod_{i=1}^n \tau^{n/2} \exp\left(-\tau \frac{\sum_{i=1}^n y_i^2}{2}\right) \times \tau^{\alpha-1} \exp(-\beta\tau)$$

1.3 Posterior predictive distribution

Figure 1.4: Beta-binomial posterior predictive distribution with corresponding binomial mass function evaluated at the maximum likelihood estimator.

and rearranging the terms to collect powers of τ , etc. we find that the posterior for τ must also be gamma, with shape parameter $\alpha^* = \alpha + n/2$ and rate $\beta^* = \beta + \sum_{i=1}^n y_i^2/2$.

The posterior predictive is

$$\begin{aligned}
 p(y_{\text{new}} | \mathbf{y}) &= \int_0^\infty \frac{\tau^{1/2}}{(2\pi)^{1/2}} \exp(-\tau y_{\text{new}}^2/2) \frac{\beta^{*\alpha^*}}{\Gamma(\alpha^*)} \tau^{\alpha^*-1} \exp(-\beta^* \tau) d\tau \\
 &= (2\pi)^{-1/2} \frac{\beta^{*\alpha^*}}{\Gamma(\alpha^*)} \int_0^\infty \tau^{\alpha^*-1/2} \exp\left\{-\tau(y_{\text{new}}^2/2 + \beta^*)\right\} d\tau \\
 &= (2\pi)^{-1/2} \frac{\beta^{*\alpha^*}}{\Gamma(\alpha^*)} \frac{\Gamma(\alpha^* + 1/2)}{(y_{\text{new}}^2/2 + \beta^*)^{\alpha^*+1/2}} \\
 &= \frac{\Gamma\left(\frac{2\alpha^*+1}{2}\right)}{\sqrt{2\pi} \Gamma\left(\frac{2\alpha^*}{2}\right) \beta^{*1/2}} \left(1 + \frac{y_{\text{new}}^2}{2\beta^*}\right)^{-\alpha^*-1/2} \\
 &= \frac{\Gamma\left(\frac{2\alpha^*+1}{2}\right)}{\sqrt{\pi} \sqrt{2\alpha^*} \Gamma\left(\frac{2\alpha^*}{2}\right) (\beta^*/\alpha^*)^{1/2}} \left(1 + \frac{1}{2\alpha^*} \frac{y_{\text{new}}^2}{(\beta^*/\alpha^*)}\right)^{-\alpha^*-1/2}
 \end{aligned}$$

which entails that Y_{new} is a scaled Student- t distribution with scale $(\beta^*/\alpha^*)^{1/2}$ and $2\alpha + n$ degrees of freedom. This example also exemplifies the additional variability relative to the

distribution generating the data: indeed, the Student- t distribution is more heavy-tailed than the Gaussian, but since the degrees of freedom increase linearly with n , the distribution converges to a Gaussian as $n \rightarrow \infty$, reflecting the added information as we collect more and more data points and the variance gets better estimated through $\sum_{i=1}^n y_i^2 / n$.

1.4 Summarizing posterior distributions

The output of the Bayesian learning problem will be either of:

1. a fully characterized distribution
2. a numerical approximation to the posterior distribution (pointwise)
3. an exact or approximate sample drawn from the posterior distribution

In the first case, we will be able to directly evaluate quantities of interest if there are closed-form expressions for the latter, or else we could draw samples from the distribution and evaluate them via Monte-Carlo. In case of numerical approximations, we will need to resort to numerical integration or otherwise to get our answers.

Often, we will also be interested in the marginal posterior distribution of each component θ_j in turn ($j = 1, \dots, J$). To get these, we carry out additional integration steps,

$$p(\theta_j | \mathbf{y}) = \int p(\boldsymbol{\theta} | \mathbf{y}) d\boldsymbol{\theta}_{-j}.$$

With a posterior sample, this is trivial: it suffices to keep the column corresponding to θ_j and discard the others.

Most of the field of Bayesian statistics revolves around the creation of algorithms that either circumvent the calculation of the normalizing constant (notably using Monte Carlo and Markov chain Monte Carlo methods) or else provide accurate numerical approximation of the posterior pointwise, including for marginalizing out all but one parameters (integrated nested Laplace approximations, variational inference, etc.) The target of inference is the whole posterior distribution, a potentially high-dimensional object which may be difficult to summarize or visualize. We can thus report only characteristics of the latter.

The choice of point summary to keep has its root in decision theory.

Definition 1.1 (Loss function). A loss function $c(\boldsymbol{\theta}, \mathbf{v})$ is a mapping from $\Theta \rightarrow \mathbb{R}^k$ that assigns a weight to each value of $\boldsymbol{\theta}$, corresponding to the regret or loss arising from choosing this value. The corresponding point estimator $\hat{\mathbf{v}}$ is the minimizer of the expected loss,

1.4 Summarizing posterior distributions

$$\begin{aligned}\hat{v} &= \underset{v}{\operatorname{argmin}} \mathbb{E}_{\Theta|Y} \{c(\theta, v)\} \\ &= \underset{v}{\operatorname{argmin}} \int_{\Theta} c(\theta, v) p(\theta | y) d\theta\end{aligned}$$

For example, in a univariate setting, the quadratic loss $c(\theta, v) = (\theta - v)^2$ returns the posterior mean, the absolute loss $c(\theta, v) = |\theta - v|$ returns the posterior median and the 0-1 loss $c(\theta, v) = \mathbb{I}(v \neq \theta)$ returns the posterior mode. All of these point estimators are central tendency measures, but some may be more adequate depending on the setting as they can correspond to potentially different values, as shown in the left-panel of Figure 1.5. The choice is application specific: for multimodal distributions, the mode is likely a better choice.

If we know how to evaluate the distribution numerically, we can optimize to find the mode or else return the value for the pointwise evaluation on a grid at which the density achieves it's maximum. The mean and median would have to be evaluated by numerical integration if there is no closed-form expression for the latter.

If we have rather a sample from the posterior with associated posterior density values, then we can obtain the mode as the parameter combination with the highest posterior, the median from the value at rank $\lfloor n/2 \rfloor$ and the mean through the sample mean of posterior draws.

The loss function is often a functional (meaning a one-dimensional summary) from the posterior. The following example shows how it reduces a three-dimensional problem into a single risk measure.

Example 1.4 (Danish insurance losses). In extreme value, we are often interested in assessing the risk of events that are rare enough that they lie beyond the range of observed data. To provide a scientific extrapolation, it often is justified to fit a generalized Pareto distribution to exceedances of $Z = Y - u$, for some user-specified threshold u which is often taken as a large quantile of the distribution of Y . The generalized Pareto distribution function is

$$F(z; \tau, \xi) = 1 - \begin{cases} (1 + \xi/\tau z)_+^{-1/\xi}, & \xi \neq 0 \\ \exp(-z/\tau), & \xi = 0. \end{cases}$$

The shape ξ governs how heavy-tailed the distribution is, while τ is a scale parameter.

1 Bayesics

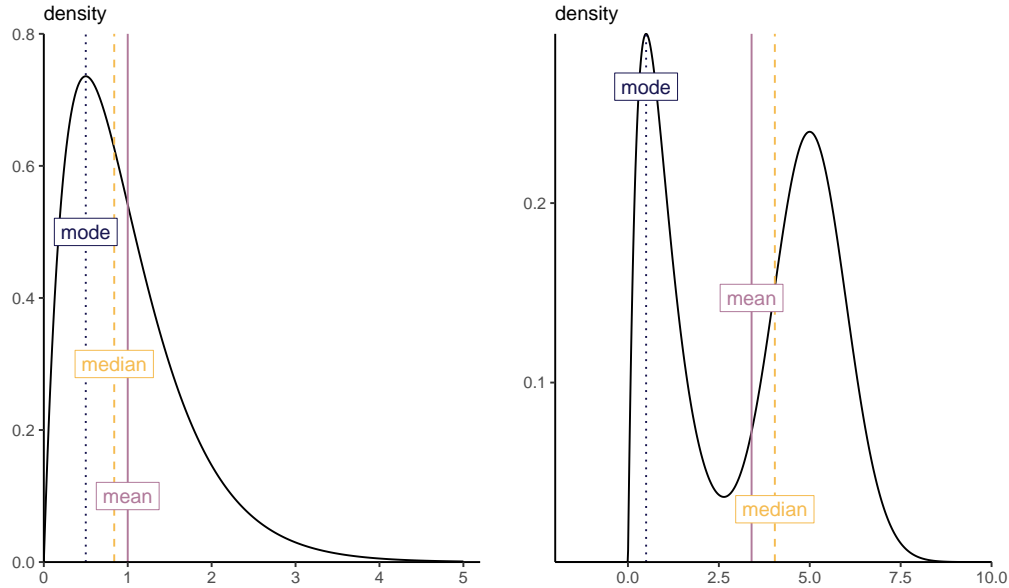

Figure 1.5: Point estimators from a right-skewed distribution (left) and from a multimodal distribution (right).

Insurance companies provide coverage in exchange for premiums, but need to safeguard themselves against very high claims by buying reinsurance products. These risks are often communicated through the value-at-risk (VaR), a high quantile exceeded with probability p . We model Danish fire insurance claim amounts for inflation-adjusted data collected from January 1980 until December 1990 that are in excess of a million Danish kroner, found in the `evir` package and analyzed in Example 7.23 of McNeil, Frey, and Embrechts (2005). These claims are denoted Y and there are 2167 observations.

We fit a generalized Pareto distribution to exceedances above 10 millions kroner, keeping 109 observations or roughly the largest 5% of the original sample. Preliminary analysis shows that we can treat data as roughly independent and identically distributed and goodness-of-fit diagnostics (not shown) for the generalized Pareto suggest that the fit is adequate for all but the three largest observations, which are (somewhat severely) underestimated by the model.

The generalized Pareto model only describes the n_u exceedances above $u = 10$, so we need to incorporate in the likelihood a binomial contribution for the probability ζ_u of exceeding the threshold u . Provided that the priors for (τ, ξ) are independent of those for ζ_u , the posterior also factorizes as a product, so ζ_u and (τ, ξ) are a posteriori independent.

Suppose for now that we set a $\text{Be}(0.5, 0.5)$ prior for ζ_u and a non-informative prior for the generalized Pareto parameters. The `post_samp` matrix contains exact samples from the

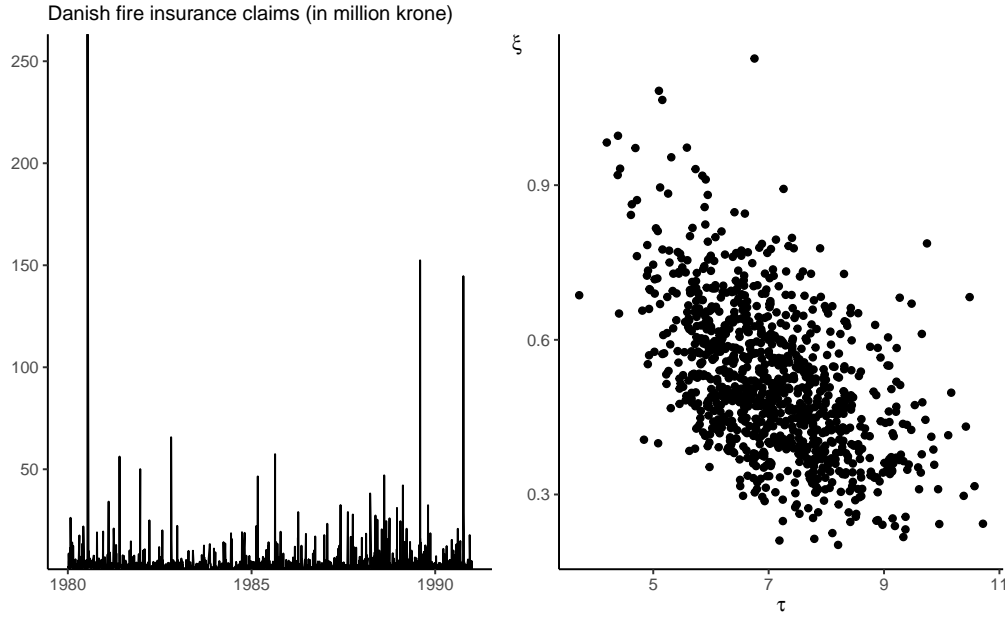

Figure 1.6: Time series of Danish fire claims exceeding a million krone (left) and posterior samples from the scale τ and shape ξ of the generalized Pareto model fitted to exceedances above 10 million krone (right).

posterior distribution of (τ, ξ, ζ_u) , obtained using a Monte Carlo algorithm. Our aim is to evaluate the posterior distribution for the value-at-risk, the α quantile of Y for high values of α and see what point estimator one would obtain depending on our choice of loss function. For any $\alpha > 1 - \zeta_u$, the q_α is

$$\begin{aligned} 1 - \alpha &= \Pr(Y > q_\alpha \mid Y > u) \Pr(Y > u) \\ &= \left(1 + \xi \frac{q_\alpha - u}{\tau}\right)^{-1/\xi} \zeta_u \end{aligned}$$

and solving for q_α gives

$$q_\alpha = u + \frac{\tau}{\xi} \left\{ \left(\frac{\zeta_u}{1 - \alpha} \right)^\xi - 1 \right\}.$$

To obtain the posterior distribution of the α quantile, q_α , it suffices to plug in each posterior sample and evaluate the function: the uncertainty is carried over from the simulated values of the parameters to those of the quantile q_α . The left panel of Figure 1.7 shows the posterior density estimate of the VaR(0.99) along with the maximum a posteriori (mode) of the latter.

1 Bayesics

Suppose that we prefer to under-estimate the value-at-risk rather than overestimate: this could be captured by the custom loss function

$$c(q, q_0) = \begin{cases} 0.5(0.99q - q_0), & q > q_0 \\ 0.75(q_0 - 1.01q), & q < q_0. \end{cases}$$

For a given value of the value-at-risk q_0 evaluated on a grid, we thus compute

$$r(q_0) = \int_{\Theta} c(q(\theta), q_0) p(\theta | \mathbf{y}) d\theta$$

and we seek to minimize the risk, $\hat{q} = \operatorname{argmin}_{q_0 \in \mathbb{R}_+} r(q_0)$. The value returned that minimizes the loss, shown in Figure 1.7, is to the left of the posterior mean for q_α .

```
# Compute value at risk from generalized Pareto distribution quantile fn
VaR_post <- with(post_samp, # data frame of posterior draws
  revdbayes::qgp( # with columns 'probexc', 'scale', 'shape'
    p = 0.01/probexc,
    loc = 10,
    scale = scale,
    shape = shape,
    lower.tail = FALSE))
# Loss function
loss <- function(qhat, q){
  mean(ifelse(q > qhat,
    0.5*(0.99*q-qhat),
    0.75*(qhat-1.01*q)))
}
# Create a grid of values over which to estimate the loss for VaR
nvals <- 101L
VaR_grid <- seq(
  from = quantile(VaR_post, 0.01),
  to = quantile(VaR_post, 0.99),
  length.out = nvals)
# Create a container to store results
risk <- numeric(length = nvals)
for(i in seq_len(nvals)){
  # Compute integral (Monte Carlo average over draws)
  risk[i] <- loss(q = VaR_post, qhat = VaR_grid[i])
}
```

To communicate uncertainty, we may resort to credible regions and intervals.

1.4 Summarizing posterior distributions

Figure 1.7: Posterior density (left) and losses functions for the 0.99 value-at-risk for the Danish fire insurance data. The vertical lines denote point estimates of the quantiles that minimize the loss functions.

Definition 1.2. A $(1 - \alpha)$ **credible region** (or credible interval in the univariate setting) is a set \mathcal{S}_α such that, with probability level α ,

$$\Pr(\boldsymbol{\theta} \in \mathcal{S}_\alpha \mid \mathbf{Y} = \mathbf{y}) = 1 - \alpha$$

These intervals are not unique, as are confidence sets. In the univariate setting, the central or equitailed interval are the most popular, and easily obtained by considering the $\alpha/2, 1 - \alpha/2$ quantiles. These are easily obtained from samples by simply taking empirical quantiles. An alternative, highest posterior density credible sets, which may be a set of disjoint intervals obtained by considering the parts of the posterior with the highest density, may be more informative. The top panel Figure 1.8 shows the distinction for a bimodal mixture distribution, and a even more striking difference for 50% credible intervals for a symmetric beta distribution whose mass lie near the endpoints of the distribution, leading to no overlap between the two intervals.

1 Bayesics

2 Priors

The posterior distribution combines two ingredients: the likelihood and the prior. If the former is a standard ingredient of any likelihood-based inference, prior specification requires some care. The purpose of this chapter is to consider different standard way of constructing prior functions, and to specify the parameters of the latter: we term these hyperparameters.

The posterior is a compromise prior and likelihood: the more informative the prior, the more the posterior resembles it, but in large samples, the effect of the prior is often negligible if there is enough information in the likelihood about all parameters. We can assess the robustness of the prior specification through a sensitivity analysis by comparing the outcomes of the posterior for different priors or different values of the hyperparameters.

We can use moment matching to get sensible values, or tune via trial-and-error using the prior predictive draws to assess the implausibility of the prior outcomes. One challenge is that even if we have some prior information (e.g., we can obtain sensible prior values for the mean, quantiles or variance of the parameter of interest), these summary statistics will not typically be enough to fully characterize the prior: many different functions or distributions could encode the same information. This means that different analysts get different inferences. Generally, we will choose the prior for convenience. Priors are controversial because they could be tuned aposteriori to give any answer an analyst might want.

2.1 Prior simulation

Expert elicitation is difficult and it is hard to grasp what the impacts of the hyperparameters are. One way to see if the priors are reasonable is to sample values from them and generate new observations, resulting in prior predictive draws.

The prior predictive is $\int_{\Theta} p(y | \theta)p(\theta)d\theta$: we can simulate outcomes from it by first drawing parameter values from the prior, then sampling new observations from the distribution in the likelihood and keeping only the latter. If there are sensible bounds for the range of the response, we could discard values that do not abide with these.

2 Priors

Working with standardized inputs $x_i \mapsto (x_i - \bar{x})/\text{sd}(x)$ is useful. For example, in a simple linear regression (with a sole numerical explanatory), the slope is the correlation between standardized explanatory X and standardized response Y and the intercept should be mean zero.

Example 2.1. Consider the daily number of Bixi bike sharing users for 2017–2019 at the Edouard Montpetit station next to HEC: we can consider a simple linear regression with log counts as a function of temperature,¹

$$\log(\text{nusers}) \sim \text{No}_+\{\beta_0 + \beta_1(\text{temp} - 20), \sigma^2\}.$$

The β_1 slope measures units in degree Celsius per log number of person.

The hyperparameters depend of course on the units of the analysis, unless one standardizes response variable and explanatories: it is easier to standardize the temperature so that we consider deviations from, say 20°C, which is not far from the observed mean in the sample. After some tuning, the independent priors $\beta_0 \sim \text{No}(\bar{y}, 0.5^2)$, $\beta_1 \sim \text{No}(0, 0.05^2)$ and $\sigma \sim \text{Exp}(3)$ seem to yield plausible outcomes and relationships.²

We can draw regression lines from the prior, as in the left panel of Figure 2.1: while some of the negative relationships appear unlikely after seeing the data, the curves all seem to pass somewhere in the cloud of point. By contrast, a silly prior is one that would result in all observations being above or below the regression line, or yield values that are much too large near the endpoints of the explanatory variable. Indeed, given the number of bikes for rental is limited (a docking station has only 20 bikes), it is also sensible to ensure that simulations do not return overly large numbers. The maximum number of daily users in the sample is 68, so priors that return simulations with more than 200 (roughly 5.3 on the log scale) are not that plausible. The prior predictive draws can help establish this and the right panel of Figure 2.1 shows that, except for the lack of correlation between temperature and number of users, the simulated values from the prior predictive are plausible even if overdispersed.

2.2 Conjugate priors

In very simple models, there may exists prior densities that result in a posterior distribution of the same family. We can thus directly extract characteristics of the posterior. Conjugate

¹If counts are Poisson, then the log transform is variance stabilizing.

²One can object to the prior parameters depending on the data, but an alternative would be to model centered data $y - \bar{y}$, in which case the prior for the intercept parameter β_0 would be zero.

Figure 2.1: Prior draws of the linear regressions with observed data superimposed (left), and draws of observations from the prior predictive distribution (in gray) against observed data (right).

priors are chosen for computational convenience and because interpretation is convenient, as the parameters of the posterior will often be some weighted average of prior and likelihood component.

Definition 2.1. A prior density $p(\theta)$ is conjugate for likelihood $L(\theta; \mathbf{y})$ if the product $L(\theta; \mathbf{y})p(\theta)$, after renormalization, is of the same parametric family as the prior.

Exponential families (including the binomial, Poisson, exponential, Gaussian distributions) admit conjugate priors³

³A distribution belongs to an exponential family with parameter vector $\theta \in \mathbb{R}^D$ if it can be written as

$$f(y; \theta) = \exp \left\{ \sum_{k=1}^K Q_k(\theta) t_k(y) + D(\theta) \right\}$$

and in particular, the support does not depend on unknown parameters. If we have an independent and identically distributed sample of observations y_1, \dots, y_n , the log likelihood is thus of the form

$$\ell(\theta) = \sum_{k=1}^K \phi_k(\theta) \sum_{i=1}^n t_k(y_i) + nD(\theta),$$

2 Priors

Example 2.2 (Conjugate prior for the binomial model). The binomial log density with y successes out of n trials is proportional to

$$y \log(p) + (n - y) \log(1 - p) = y \log\left(\frac{p}{1 - p}\right) + n \log(1 - p)$$

with canonical parameter $\text{logit}(p)$.⁴ The binomial distribution is thus an exponential family.

Since the density of the binomial is of the form $p^y(1 - p)^{n-y}$, the beta distribution $\text{Be}(\alpha, \beta)$ with density

$$f(x) \propto x^{\alpha-1}(1 - x)^{\beta-1}$$

is the conjugate prior.

The beta distribution is also the conjugate prior for the negative binomial, geometric and Bernoulli distributions, since their likelihoods are all proportional to that of the beta. The fact that different sampling schemes that result in proportional likelihood functions give the same inference is called likelihood principle.

Example 2.3 (Conjugate prior for the Poisson model). The Poisson distribution with mean μ has log density proportional to $f(y; \mu) \propto y \log(\mu) - \mu$, so is an exponential family with natural parameter $\log(\mu)$. The gamma density,

$$f(x) \propto \beta^\alpha / \Gamma(\alpha) x^{\alpha-1} \exp(-\beta x)$$

with shape α and rate β is the conjugate prior for the Poisson. For an n -sample of independent observations $\text{Po}(\mu)$ observations with $\mu \sim \text{Ga}(\alpha, \beta)$, the posterior is $\text{Ga}(\sum_{i=1}^n y_i + \alpha, \beta + n)$.

where the collection $\sum_{i=1}^n t_k(y_i)$ ($k = 1, \dots, K$) are sufficient statistics and $\phi_k(\theta)$ are the canonical parameters. The number of sufficient statistics are the same regardless of the sample size. Exponential families play a prominent role in generalized linear models, in which the natural parameters are modeled as linear function of explanatory variables. A log prior density with parameters $\eta, \nu_1, \dots, \nu_K$ that is proportional to

$$\log p(\theta) \propto \eta D(\theta) + \sum_{k=1}^K Q_k(\theta) \nu_k$$

is conjugate.

⁴The canonical link function for Bernoulli gives rise to logistic regression model.

Knowing the analytic expression for the posterior can be useful for calculations of the marginal likelihood, as Example 2.4 demonstrates.

Example 2.4 (Negative binomial as a Poisson mixture).

One restriction of the Poisson model is that the restriction on its moments is often unrealistic. The most frequent problem encountered is that of **overdispersion**, meaning that the variability in the counts is larger than that implied by a Poisson distribution.

One common framework for handling overdispersion is to have $Y \mid \Lambda = \lambda \sim \text{Po}(\lambda)$, where the mean of the Poisson distribution is itself a positive random variable with mean μ , if Λ follows a conjugate gamma distribution with shape $k\mu$ and rate $k > 0$, $\Lambda \sim \text{Ga}(k\mu, k)$, the posterior $\Lambda \mid Y = y \sim \text{Ga}(k\mu + y, k + 1)$.

Since the joint density of Y and Λ can be written

$$p(y, \lambda) = p(y \mid \lambda)p(\lambda) = p(\lambda \mid y)p(y)$$

we can isolate the marginal density

$$\begin{aligned} p(y) &= \frac{p(y \mid \lambda)p(\lambda)}{p(\lambda \mid y)} \\ &= \frac{\frac{\lambda^y \exp(-\lambda)}{\Gamma(y+1)} \frac{k^{k\mu} \lambda^{k\mu-1} \exp(-k\lambda)}{\Gamma(k\mu)}}{\frac{(k+1)^{k\mu+y} \lambda^{k\mu+y-1} \exp\{-(k+1)\lambda\}}{\Gamma(k\mu+y)}} \\ &= \frac{\Gamma(k\mu + y)}{\Gamma(k\mu)\Gamma(y+1)} k^{k\mu} (k+1)^{-k\mu-y} \\ &= \frac{\Gamma(k\mu + y)}{\Gamma(k\mu)\Gamma(y+1)} \left(1 - \frac{1}{k+1}\right)^{k\mu} \left(\frac{1}{k+1}\right)^y \end{aligned}$$

and this is the density of a negative binomial distribution with probability of success $1/(k+1)$. We can thus view the negative binomial as a Poisson mean mixture.

By the laws of iterated expectation and iterative variance,

$$\begin{aligned} \mathbb{E}(Y) &= \mathbb{E}_\Lambda\{\mathbb{E}(Y \mid \Lambda)\} \\ &= \mathbb{E}(\Lambda) = \mu \\ \text{Va}(Y) &= \mathbb{E}_\Lambda\{\text{Va}(Y \mid \Lambda)\} + \text{Va}_\Lambda\{\mathbb{E}(Y \mid \Lambda)\} \\ &= \mathbb{E}(\Lambda) + \text{Va}(\Lambda) \\ &= \mu + \mu/k. \end{aligned}$$

2 Priors

The marginal distribution of Y , unconditionally, has a variance which exceeds its mean, as

$$E(Y) = \mu, \quad \text{Va}(Y) = \mu(1 + 1/k).$$

In a negative binomial regression model, the term k is a dispersion parameter, which is fixed for all observations, whereas $\mu = \exp(\beta\mathbf{X})$ is a function of covariates \mathbf{X} . As $k \rightarrow \infty$, the distribution of Λ degenerates to a constant at μ and we recover the Poisson model.

Example 2.5 (Posterior rates for A/B tests using conjugate Poisson model). Upworthy.com, a US media publisher, revolutionized headlines online advertisement by running systematic A/B tests to compare the different wording of headlines, placement and image and what catches attention the most. The Upworthy Research Archive (Matias et al. 2021) contains results for 22743 experiments, with a click through rate of 1.58% on average and a standard deviation of 1.23%. The `clickability_test_id` gives the unique identifier of the experiment, `clicks` the number of conversion out of `impressions`. See Section 8.5 of Alexander (2023) for more details about A/B testing and background information.

Consider an A/B test from November 23st, 2014, that compared four different headlines for a story on Sesame Street workshop with interviews of children whose parents were in jail and visiting them in prisons. The headlines tested were:

1. Some Don't Like It When He Sees His Mom. But To Him? Pure Joy. Why Keep Her From Him?
2. They're Not In Danger. They're Right. See True Compassion From The Children Of The Incarcerated.
3. Kids Have No Place In Jail ... But In This Case, They *Totally* Deserve It.
4. Going To Jail *Should* Be The Worst Part Of Their Life. It's So Not. Not At All.

At first glance, the first and third headlines seem likely to lead to a curiosity gap. The wording of the second is more explicit (and searchable), whereas the first is worded as a question.

We model the conversion rate λ_i for each headline separately using a Poisson distribution and compare the posterior distributions for all four choices. Using a conjugate prior and selecting the parameters by moment matching yields approximately $\alpha = 1.64$ and $\beta = 0.01$ for the hyperparameters.

We can visualize the posterior distributions. In this context, the large sample size lead to the dominance of the likelihood contribution $p(Y_i | \lambda_i) \sim \text{Po}(n_i \lambda_i)$ relative to the prior. We can see there is virtually no overlap between different rates for headers H1 (preferred) relative to H4 (least favorable). The probability that the conversion rate for Headline 3 is higher

Table 2.1: Number of views, clicks for different headlines for the Upworthy data.

headline	impressions	clicks
H1	3060	49
H2	2982	20
H3	3112	31
H4	3083	9

Figure 2.2: Gamma posterior for conversion rate of the different Upworthy Sesame Street headline.

than Headline 1 can be approximated by simulating samples from both posteriors and computing the proportion of times one is larger: we get 1.7% for H3 relative to H1, indicating a clear preference for the first headline H1.

Example 2.6 (Should you phrase your headline as a question?). We can also consider aggregate records for Upworthy, as Alexander (2023) did. The `upworthy_question` database contains a balanced sample of all headlines where at least one of the choices featured a question, with at least one alternative statement. Whether a headline contains a question or not is determined by querying for the question mark. We consider aggregated counts for

2 Priors

all such headlines, with the `question` factor encoding whether there was a question, yes or no. For simplicity, we treat the number of views as fixed, but keep in mind that A/B tests are often sequential experiments with a stopping rule.⁵

We model first the rates using a Poisson regression; the corresponding frequentist analysis would include an offset to account for differences in views. If λ_j ($j = 1, 2$) are the average rate for each factor level (yes and no), then $E(Y_{ij}/n_{ij}) = \lambda_j$. In the frequentist setting, we can fit a simple Poisson generalized linear regression model with an offset term and a binary variable.

```
data(upworthy_question, package = "hecbayes")
poismod <- glm(
  clicks ~ offset(log(impressions)) + question,
  family = poisson(link = "log"),
  data = upworthy_question)
coef(poismod)
#> (Intercept)    questionno
#>      -4.5126         0.0707
```

The coefficients represent the difference in log rate (multiplicative effect) relative to the baseline rate, with an increase of 6.3 percent when the headline does not contain a question. A likelihood ratio test can be performed by comparing the deviance of the null model (intercept-only), indicating strong evidence that including question leads to significantly different rates. This is rather unsurprising given the enormous sample sizes.

Consider instead a Bayesian analysis with conjugate prior: we model separately the rates of each group (question or not). Suppose we think apriori that the click-rate is on average 1%, with a standard deviation of 2%, with no difference between questions or not. For a $\text{Ga}(\alpha, \beta)$ prior, this would translate, using moment matching, into a rate of $\beta = 0.04 = \text{Var}_0(\lambda_j)/E_0(\lambda_j)$ and a shape of $\alpha = 2.5$ ($j = 1, 2$). If λ_j is the average rate for each factor level (yes and no), then $E(Y_{ij}/n_{ij}) = \lambda_j$ so the log likelihood is proportional, as a function of λ_1 and λ_2 , to

$$\ell(\boldsymbol{\lambda}; \mathbf{y}, \mathbf{n}) \propto \sum_{i=1}^n \sum_{j=1}^2 y_{ij} \log \lambda_j - \lambda_j n_{ij}$$

and we can recognize that the posterior for λ_i is gamma with shape $\alpha + \sum_{i=1}^n y_{ij}$ and rate $\beta + \sum_{i=1}^n n_{ij}$. For inference, we thus only need to select hyperparameters and calculate the total number of clicks and impressions per group. We can then consider the posterior difference $\lambda_1 - \lambda_2$ or, to mimic the Poisson multiplicative model, of the ratio λ_1/λ_2 . The

⁵The stopping rule means that data stops being collected once there is enough evidence to determine if an option is more suitable, or if a predetermined number of views has been reached.

former suggests very small differences, but one must keep in mind that rates are also small. The ratio, shown in the right-hand panel of Figure 2.3, gives a more easily interpretable portrait that is in line with the frequentist analysis.

Figure 2.3: Histograms of posterior summaries for differences (left) and rates (right) based on 1000 simulations from the independent gamma posteriors.

To get an approximation to the posterior mean of the ratio λ_1/λ_2 , it suffices to draw independent observations from their respective posterior, compute the ratio and take the sample mean of those draws. We can see that the sampling distribution of the ratio is nearly symmetrical, so we can expect Wald intervals to perform well should one be interested in building confidence intervals. This is however hardly surprising given the sample size at play.

Example 2.7 (Conjugate prior for Gaussian mean with known variance). Consider an n simple random sample of independent and identically distributed Gaussian variables with mean μ and standard deviation σ , denoted $Y_i \sim \text{No}(\mu, \sigma^2)$. We pick a Gaussian prior for the location parameter, $\mu \sim \text{No}(\nu, \tau^2)$ where we assume μ, τ are fixed hyperparameter values. For now, we consider only inference for $p(\mu \mid \sigma)$: discarding any term that is not a function

2 Priors

of μ , the conditional posterior is

$$\begin{aligned} p(\mu \mid \sigma) &\propto \exp \left\{ -\frac{1}{2\sigma^2} \sum_{i=1}^n (y_i - \mu)^2 \right\} \exp \left\{ -\frac{1}{2\tau^2} (\mu - \nu)^2 \right\} \\ &\propto \exp \left\{ \left(\frac{\sum_{i=1}^n y_i}{\sigma^2} + \frac{\nu}{\tau^2} \right) \mu - \left(\frac{n}{2\sigma^2} + \frac{1}{2\tau^2} \right) \mu^2 \right\}. \end{aligned}$$

The log of the posterior density conditional on σ is quadratic in μ , it must be a Gaussian distribution truncated over the positive half line. This can be seen by completing the square in μ , or by comparing this expression to the density of $\text{No}(\mu, \sigma^2)$,

$$f(x; \mu, \sigma) \propto \exp \left(-\frac{1}{2\sigma^2} \mu^2 + \frac{x}{\sigma^2} \mu \right)$$

we can deduce by matching mean and variance that the conditional posterior $p(\mu \mid \sigma)$ is Gaussian with reciprocal variance (precision) $n/\sigma^2 + 1/\tau^2$ and mean $(n\bar{y}\tau^2 + \nu\sigma^2)/(n\tau^2 + \sigma^2)$. The precision is an average of that of the prior and data, but assigns more weight to the latter, which increases linearly with the sample size n . Likewise, the posterior mean is a weighted average of prior and sample mean, with weights proportional to the relative precision.

The exponential family is quite large; Fink (1997) *A Compendium of Conjugate Priors* gives multiple examples of conjugate priors and work out parameter values.

In general, unless the sample size is small and we want to add expert opinion, we may wish to pick an *uninformative prior*, i.e., one that does not impact much the outcome. For conjugate models, one can often show that the relative weight of prior parameters (relative to the random sample likelihood contribution) becomes negligible by investigating their relative weights.

2.3 Uninformative priors

Definition 2.2 (Proper prior). We call a prior function *proper* if its integral is finite over the parameter space; such prior function automatically leads to a valid posterior.

The best example of prior priors arise from probability density function. We can still employ this rule for improper priors: for example, taking $\alpha, \beta \rightarrow 0$ in the beta prior leads to a prior proportional to $x^{-1}(1-x)^{-1}$, the integral of which diverges on the unit interval $[0, 1]$.

However, as long as the number of success and the number of failures is larger than 1, meaning $k \geq 1, n - k \geq 1$, the posterior distribution would be proper, i.e., integrable. To find the posterior, normalizing constants are also superfluous.

Many uninformative priors are flat, or proportional to a uniform on some subset of the real line and therefore improper. It may be superficially tempting to set a uniform prior on a large range to ensure posterior property, but the major problem is that a flat prior may be informative in a different parametrization, as the following example suggests.

Gelman et al. (2013) uses the following taxonomy for various levels of prior information: uninformative priors are generally flat or uniform priors with $p(\beta) \propto 1$, vague priors are typically nearly flat even if proper, e.g., $\beta \sim \text{No}(0, 100)$, weakly informative priors provide little constraints $\beta \sim \text{No}(0, 10)$, and informative prior are typically application-specific, but constrain the ranges. Uninformative and vague priors are generally not recommended unless they are known to give valid posterior inference and the amount of information from the likelihood is high.

Example 2.8 (Transformation of flat prior for scales). Consider the parameter $\log(\tau) \in \mathbb{R}$ and the prior $p(\log \tau) \propto 1$. If we reparametrize the model in terms of τ , the new prior (including the Jacobian of the transformation) is τ^{-1}

Some priors are standard and widely used. In location scale families with location ν and scale τ , the density is such that

$$f(x; \nu, \tau) = \frac{1}{\tau} f\left(\frac{x - \nu}{\tau}\right), \quad \nu \in \mathbb{R}, \tau > 0.$$

We thus wish to have a prior so that $p(\tau) = c^{-1}p(\tau/c)$ for any scaling $c > 0$, whence it follows that $p(\tau) \propto \tau^{-1}$, which is uniform on the log scale.

The priors $p(\nu) \propto 1$ and $p(\tau) \propto \tau^{-1}$ are both improper but lead to location and scale invariance, hence that the result is the same regardless of the units of measurement.

One criticism of the Bayesian approach is the arbitrariness of prior functions. However, the role of the prior is often negligible in large samples (consider for example the posterior of exponential families with conjugate priors). Moreover, the likelihood is also chosen for convenience, and arguably has a bigger influence on the conclusion. Data fitted using a linear regression model seldom follow Gaussian distributions conditionally, in the same way that the linearity is a convenience (and first order approximation).

2 Priors

Definition 2.3 (Jeffrey's prior). In single parameter models, taking a prior function for θ proportional to the square root of the determinant of the information matrix, $p(\theta) \propto |i(\theta)|^{1/2}$ yields a prior that is invariant to reparametrization, so that inferences conducted in different parametrizations are equivalent.⁶

To see this, consider a bijective transformation $\theta \mapsto \vartheta$. Under the reparametrized model and suitable regularity conditions⁷, the chain rule implies that

$$\begin{aligned} i(\vartheta) &= -\mathbb{E} \left(\frac{\partial^2 \ell(\vartheta)}{\partial^2 \vartheta} \right) \\ &= -\mathbb{E} \left(\frac{\partial^2 \ell(\theta)}{\partial \theta^2} \right) \left(\frac{d\theta}{d\vartheta} \right)^2 + \mathbb{E} \left(\frac{\partial \ell(\theta)}{\partial \theta} \right) \frac{d^2 \theta}{d\vartheta^2} \end{aligned}$$

Since the score has mean zero, $\mathbb{E} \{ \partial \ell(\theta) / \partial \theta \} = 0$ and the rightmost term vanishes. We can thus relate the Fisher information in both parametrizations, with

$$i^{1/2}(\vartheta) = i^{1/2}(\theta) \left| \frac{d\theta}{d\vartheta} \right|,$$

implying invariance.

In multiparameter models, the system isn't invariant to reparametrization if we consider the determinant of the Fisher information.

Example 2.9 (Jeffrey's prior for the binomial distribution). Consider the binomial distribution $\text{Bin}(1, \theta)$ with density $f(y; \theta) \propto \theta^y (1 - \theta)^{1-y} \mathbf{1}_{\theta \in [0,1]}$. The negative of the second derivative of the log likelihood with respect to θ is

$$j(\theta) = -\partial^2 \ell(\theta; y) / \partial \theta^2 = y/\theta^2 + (1 - y)/(1 - \theta)^2$$

and since $\mathbb{E}(Y) = \theta$, the Fisher information is

$$i(\vartheta) = \mathbb{E}\{j(\theta)\} = 1/\theta + 1/(1 - \theta) = 1/\{\theta(1 - \theta)\}$$

Jeffrey's prior is thus $p(\theta) \propto \theta^{-1/2} (1 - \theta)^{-1/2}$, a conjugate Beta prior $\text{Be}(0.5, 0.5)$.

⁶The Fisher information is linear in the sample size for independent and identically distributed data so we can derive the result for $n = 1$ without loss of generality.

⁷Using Bartlett's identity; Fisher consistency can be established using the dominated convergence theorem.

2.4 Jeffrey's prior for the normal distribution

Check that for the Gaussian distribution $\text{No}(\mu, \sigma^2)$, the Jeffrey's prior obtained by treating each parameter as fixed in turn, are $p(\mu) \propto 1$ and $p(\sigma) \propto 1/\sigma$, which also correspond to the default uninformative priors for location-scale families.

Example 2.10 (Jeffrey's prior for the Poisson distribution). The Poisson distribution with $\ell(\lambda) \propto -\lambda + y \log \lambda$, with second derivative $-\partial^2 \ell(\lambda)/\partial \lambda^2 = y/\lambda^2$. Since the mean of the Poisson distribution is λ , the Fisher information is $\iota(\lambda) = \lambda^{-1}$ and Jeffrey's prior is $\lambda^{-1/2}$.

2.5 Informative priors

One strength of the Bayesian approach is the capability of incorporating expert and domain-based knowledge through priors. Often, these will take the form of moment constraints, so one common way to derive a prior is to perform moment matching to related elicited quantities with moments of the prior distribution. It may be easier to set priors on a different scale than those of the observations, as Example 2.11 demonstrates.

Example 2.11 (Gamma quantile difference priors for extreme value distributions). The generalized extreme value distribution arises as the limiting distribution for the maximum of m independent observations from some common distribution F . The $\text{GEV}(\mu, \sigma, \xi)$ distribution is a location-scale with distribution function

$$F(x) = \exp \left[- \{1 + \xi(x - \mu)/\sigma\}_+^{-1/\xi} \right]$$

where $x_+ = \max\{0, x\}$.

Inverting the distribution function yields the quantile function

$$Q(p)\mu + \sigma \frac{(-\log p)^{-\xi} - 1}{\xi}$$

In environmental data, we often model annual maximum. Engineering designs are often specified in terms of the k -year return levels, defined as the quantile of the annual maximum exceeded with probability $1/k$ in any given year. Using a GEV for annual maximum, Coles and Tawn (1996) proposed modelling annual daily rainfall and specifying a prior on the

2 Priors

quantile scale $q_1 < q_2 < q_3$ for tail probabilities $p_1 > p_2 > p_3$. To deal with the ordering constraints, gamma priors are imposed on the differences $q_1 - o \sim \text{Ga}(\alpha_1, \beta_1)$, $q_2 - q_1 \sim \text{Ga}(\alpha_2, \beta_2)$ and $q_3 - q_2 \sim \text{Ga}(\alpha_3, \beta_3)$, where o is the lower bound of the support. The prior is thus of the form

$$p(\mathbf{q}) \propto q_1^{\alpha_1-1} \exp(-\beta_1 q_1) \prod_{i=2}^3 (q_i - q_{i-1})^{\alpha_i-1} \exp\{\beta_i (q_i - q_{i-1})\}.$$

where $0 \leq q_1 \leq q_2 \leq q_3$. The fact that these quantities refer to moments or risk estimates which practitioners often must compute as part of regulatory requirements makes it easier to specify sensible values for hyperparameters.

As illustrating example, consider maximum daily cumulated rainfall in Abisko, Sweden. The time series spans from 1913 until December 2014; we compute the 102 yearly maximum, which range from 11mm to 62mm, and fit a generalized extreme value distribution to these.

For the priors, suppose an expert elicits quantiles of the 10, 50 and 100 years return levels; say 30mm, 45mm and 70mm, respectively, for the median and likewise 40mm, 70mm and 120mm for the 90% percentile of the return levels. We can compute the differences and calculate the parameters of the gamma distribution through moment-matching: this gives roughly a shape of $\alpha_1 = 18.27$ and $\beta_1 = 0.6$, etc. Figure 2.4 shows the transfer from the prior predictive to the posterior distribution. The prior is much more dispersed and concentrated on the tail, which translates in a less peaked posterior than using a weakly informative prior (dotted line): the mode of the latter is slightly to the left and with lower density in the tail.

What would you do if we you had prior information from different sources? One way to combine these is through a mixture: given M different prior distributions $p_m(\boldsymbol{\theta})$, we can assign each a positive weight w_m to form a mixture of experts prior through the linear combination

$$p(\boldsymbol{\theta}) \propto \sum_{m=1}^M w_m p_m(\boldsymbol{\theta})$$

2.5.1 Penalized complexity priors

Oftentimes, there will be a natural family of prior density to impose on some model component, $p(\boldsymbol{\theta} \mid \zeta)$, with hyperparameter ζ . The flexibility of the underlying construction leads itself to overfitting. Penalized complexity priors (Simpson et al. 2017) aim to palliate this by penalizing models far away from a simple baseline model, which correspond to a fixed value ζ_0 . The prior will favour the simpler parsimonious model the more prior mass one places on ζ_0 , which is in line with Occam's razor principle.

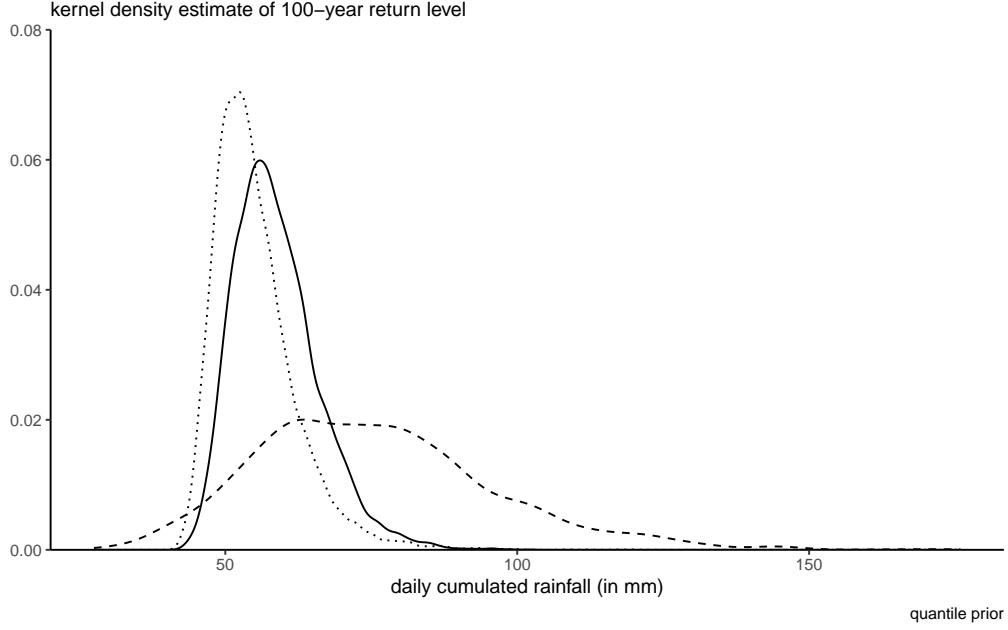

Figure 2.4: Kernel density estimates of draws from the posterior distribution of 100 year return levels with a Coles–Tawn quantile prior (full line) and from the corresponding prior predictive (dashed). The dotted line gives the posterior distribution for a maximum domain information prior on the shape with improper priors on location and scale.

To construct a penalized-complexity prior, we compute the Kullback–Leibler divergence between the model $p_\zeta \equiv p(\boldsymbol{\theta} \mid \zeta)$ relative to the baseline with ζ_0 , $p_0 \equiv p(\boldsymbol{\theta} \mid \zeta_0)$; the Kullback–Leibler divergence is

$$\text{KL}(p_\zeta \parallel p_0) = \int p_\zeta \log \left(\frac{p_\zeta}{p_0} \right) d\boldsymbol{\theta}.$$

The distance between the prior densities is then set to $d(\zeta) = \{2\text{KL}(p_\zeta \parallel p_0)\}^{1/2}$, which is zero at the model with ζ_0 . The PC prior then constructs an exponential prior on the distance scale, which after back-transformation gives $p(\zeta \mid \lambda) = \lambda \exp(-\lambda d(\zeta)) \left| \partial d(\zeta) / \partial \zeta \right|$. To choose λ , the authors recommend elicitation of a pair (U, α) such that $\Pr(\lambda > U) = \alpha$.

Example 2.12 (Penalized complexity prior for random effects models). Simpson et al. (2017) give the example of a Gaussian prior for random effects α , of the form $\alpha \mid \zeta \sim \text{No}_J(\mathbf{0}_J, \zeta^2 \mathbf{I}_J)$ where $\zeta_0 = 0$ corresponds to the absence of random subject-variability. The penalized

2 Priors

complexity prior for the scale ζ is then an exponential with rate λ ,⁸ with density $p(\zeta \mid \lambda) = \lambda \exp(-\lambda\zeta)$. Using the recommendation for setting λ , we get that $\lambda = -\ln(\alpha/U)$ and this can be directly interpreted in terms of standard deviation of ζ ; simulation from the prior predictive may also be used for calibration.

Example 2.13 (Penalized complexity prior for autoregressive model of order 1). Sørbye and Rue (2017) derive penalized complexity prior for the Gaussian stationary AR(1) model with autoregressive parameter $\phi \in (-1, 1)$, where $Y_t \mid Y_{t-1}, \phi, \sigma^2 \sim \text{No}(\phi Y_{t-1}, \sigma^2)$. There are two based models that could be of interest: one with $\phi = 0$, corresponding to a memoryless model with no autocorrelation, and a static mean $\phi = 1$ for no change in time; note that the latter is not stationary. For the former, the penalized complexity prior is

$$p(\phi \mid \lambda) = \frac{\lambda}{2} \exp \left[-\lambda \left\{ -\ln(1 - \phi^2) \right\}^{1/2} \right] \frac{|\phi|}{(1 - \phi^2) \left\{ -\ln(1 - \phi^2) \right\}^{1/2}}.$$

One can set λ by considering plausible values by relating the parameter to the variance of the one-step ahead forecast error.

Gaussian components are widespread: not only for linear regression models, but more generally for the specification of random effects that capture group-specific effects, residuals spatial or temporal variability. In the Bayesian paradigm, there is no difference between fixed effects β and the random effect parameters: both are random quantities that get assigned priors, but we will treat these priors differently.

The reason why we would like to use a penalized complexity prior for a random effect, say $\alpha_j \sim \text{No}(0, \zeta^2)$, is because we don't know a priori if there is variability between groups. The inverse gamma prior for ζ , $\zeta \sim \text{IGa}(\epsilon, \epsilon)$ does not have a mode at zero unless it is improper with $\epsilon \rightarrow 0$. Generally, we want our prior for the variance to have significant probability density at the null $\zeta = 0$. The penalized complexity prior is not the only sensible choice. Posterior inference is unfortunately sensitive to the value of ϵ in hierarchical models when the random effect variance is close to zero, and more so when there are few levels for the groups since the relative weight of the prior relative to that of the likelihood contribution is then large.

Example 2.14 (Student- t prior for variance components). Gelman (2006) recommends a Student- t distribution truncated below at 0, with low degrees of freedom. The rationale

⁸Possibly truncated above if the support of ζ has a finite upper bound.

for this choice comes from the simple two level model with n_j independent in each group $j = 1, \dots, J$: for observation i in group j ,

$$\begin{aligned} Y_{ij} &\sim \text{No}(\mu + \alpha_j, \sigma^2), \\ \alpha_j &\sim \text{No}(0, \tau_\alpha^2), \end{aligned}$$

The conditionally conjugate prior $p(\tau \mid \alpha, \mu, \sigma)$ is inverse gamma. Standard inference with this parametrization is however complicated, because there is strong dependence between parameters.

To reduce this dependence, one can add a parameter, taking $\alpha_j = \xi \eta_j$ and $\tau_\alpha = |\xi| \tau_\eta$; the model is now overparametrized. Suppose $\eta_j \sim \text{No}(0, \tau_\eta^2)$ and consider the likelihood conditional on μ, η_j : we have that $(y_{ij} - \mu)/\eta_j \sim \text{No}(\xi, \sigma^2/\eta_j)$ so conditionally conjugate priors for ξ and τ_η are respectively Gaussian and inverse gamma. This translates into a prior distribution for τ_α which is that of the absolute value of a noncentral Student- t with location, scale and degrees of freedom ν . If we set the location to zero, the prior puts high mass at the origin, but is heavy tailed with polynomial decay. We recommend to set degrees of freedom so that the variance is heavy-tailed, e.g., $\nu = 3$. While this prior is not conjugate, it compares favorably to the $\text{lGa}(\epsilon, \epsilon)$.

Example 2.15 (Poisson random effect models). We consider data from an experimental study conducted at Tech3Lab on road safety. In Brodeur et al. (2021), 31 participants were asked to drive in a virtual environment; the number of road violation was measured for different type of distractions (phone notification, phone on speaker, texting and smartwatch). The data are balanced, with each participant exposed to each task exactly once.

We model the data using a Poisson mixed model to measure the number of violations, `nviolation`, with a fixed effect for `task`, which captures the type of distraction, and a random effect for participant `id`. The hierarchical model fitted for individual i ($i = 1, \dots, 34$) and distraction type j ($j = 1, \dots, 4$) is

$$\begin{aligned} Y_{ij} &\sim \text{Po}\{\mu = \exp(\beta_j + \alpha_i)\}, \\ \beta_j &\sim \text{No}(0, 100), \\ \alpha_i &\sim \text{No}(0, \kappa^2), \\ \kappa &\sim \text{St}_+(3). \end{aligned}$$

so observations are conditionally independent given hyperparameters α and β .

In frequentist statistics, there is a distinction made in mixed-effect models between parameters that are treated as constants, termed fixed effects and corresponding in this example

2 Priors

to β , and random effects, equivalent to α . There is no such distinction in the Bayesian paradigm, except perhaps for the choice of prior.

We can look at some of posterior distribution of the 31 random effects (here the first five individuals) and the fixed effect parameters β , plus the variance of the random effect κ : there is strong evidence that the latter is non-zero, suggesting strong heterogeneity between individuals. The distraction which results in the largest number of violation is texting, while the other conditions all seem equally distracting on average (note that there is no control group with no distraction to compare with, so it is hard to draw conclusions).

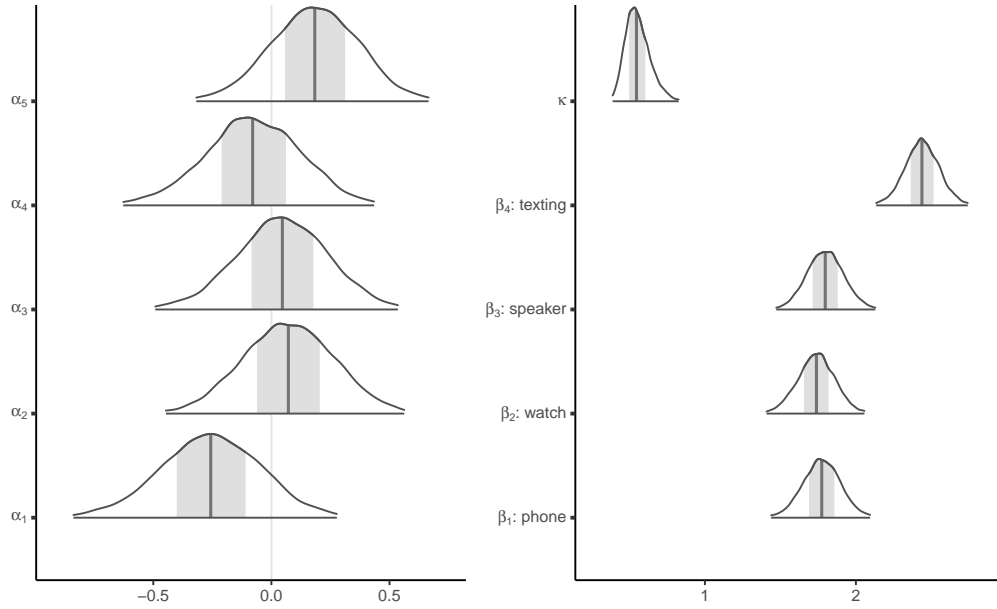

Figure 2.5: Posterior density plots with 50% credible intervals and median value for the random effects of the first five individuals (left) and the fixed effects and random effect variance (right).

2.6 Sensitivity analysis

Do priors matter? The answer to that question depends strongly on the model, and how much information the data provides about hyperparameters. While this question is easily answered in conjugate models (the relative weight of hyperparameters relative to data can be derived from the posterior parameters), it is not so simple in hierarchical models, where the interplay between prior distributions is often more intricate. To see the impact, one often has to rely on doing several analyses with different values for the prior and see the

sensitivity of the conclusions to these changes, for example by considering a vague prior or modifying the parameters values (say halving or doubling). If the changes are immaterial, then this provides reassurance that our analyses are robust.

Example 2.16. To check the sensitivity of the conclusion, we revisit the modelling of the smartwatch experiment data using a Poisson regression and compare four priors: a uniform prior truncated to $[0, 10]$, an inverse gamma $IG(0.01, 0.01)$ prior, a penalized complexity prior such that the 0.95 percentile of the scale is 5, corresponding to $\text{Exp}(0.6)$. Since each distraction type appears 31 times, there is plenty of information to reliably estimate the dispersion κ of the random effects α : the different density plots in Figure 2.6 are virtually indistinguishable from one another. This is perhaps unsurprising given the large number of replicates, and the significant variability between groups.

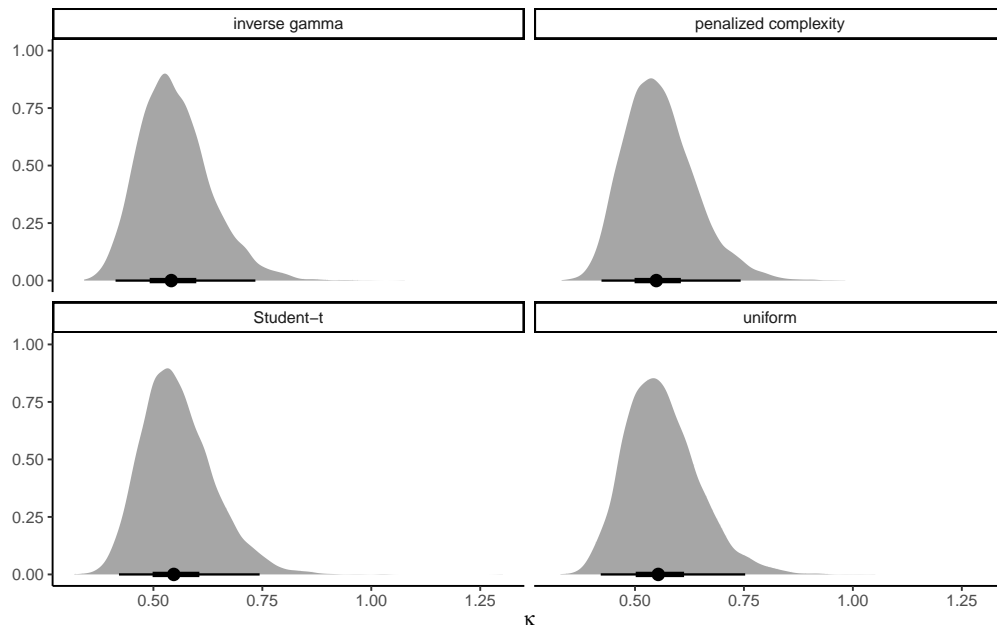

Figure 2.6: Posterior density of the scale of the random effects with uniform, inverse gamma, penalized complexity and folded Student-t with three degrees of freedom. The circle denotes the median and the bars the 50% and 95% percentile credible intervals.

3 Simulation-based inference

There are two major approaches to handling the problem of the unknown normalizing constant: deterministic and stochastic approximations. The former includes Laplace and nested Laplace approximations, variational methods and expectation propagation. This chapter covers the latter, stochastic approximations, and focuses on implementation of basic Markov chain Monte Carlo algorithms. The simulation algorithms circumvent the need to calculate the normalizing constant of the posterior entirely. We present several examples of implementations, several tricks for tuning and diagnostics of convergence.

3.1 Monte Carlo methods

Consider a target distribution with finite expected value: think of the posterior of some model of interest, or some functional thereof. The law of large numbers guarantees that, if we can draw observations from our target distribution, then the sample average will converge to the expected value of that distribution, as the sample size becomes larger and larger, provided the expectation is finite.

We can thus compute the probability of any event or the expected value of any (integrable) function by computing sample averages; the cost to pay for this generality is randomness.

Specifically, suppose we are interested in the average $E\{g(X)\}$ of $X_i \sim F$ for some function g .

Example 3.1. Consider $X \sim \text{Ga}(\alpha, \beta)$, a gamma distribution with shape α and rate β . We can compute the probability that $X < 1$ easily by Monte Carlo since $\Pr(X < 1) = E\{\mathbf{I}(X < 1)\}$ and this means we only need to compute the proportion of draws less than one. We can likewise compute the mean $g(x) = x$ or variance.

Suppose we have drawn a Monte Carlo sample of size B . If the function $g(\cdot)$ is square integrable,¹ with variance σ_g^2 , then a central limit theorem applies. In large samples and

¹Meaning $E\{g^2(X)\} < \infty$, so the variance of $g(X)$ exists.

3 Simulation-based inference

for independent observations, our Monte Carlo average $\hat{\mu}_g = B^{-1} \sum_{b=1}^B g(X_i)$ has variance σ_g^2/B . We can approximate the unknown variance σ_g^2 by its empirical counterpart.² Note that, while the variance decreases linearly with B , the choice of g impacts the speed of convergence: we can compute $\sigma_g^2 = \Pr(X \leq 1)\{1 - \Pr(X \leq 1)\} = 0.0434$ (left) and $\sigma_g^2 = \alpha/\beta^2 = 1/8$ (middle plot).

Figure 3.1 shows the empirical trace plot of the Monte Carlo average (note the \sqrt{B} x -axis scale!) as a function of the Monte Carlo sample size B along with 95% Wald-based confidence intervals (gray shaded region), $\hat{\mu}_g \pm 1.96 \times \sigma_g/\sqrt{B}$. We can see that the ‘likely region’ for the average shrinks with B .

What happens if our function is not integrable? The right-hand plot of Figure 3.1 shows empirical averages of $g(x) = x^{-1}$, which is not integrable if $\alpha < 1$. We can compute the empirical average, but the result won’t converge to any meaningful quantity regardless of the sample size. The large jumps are testimonial of this.

Figure 3.1: Running mean trace plots for $I(x < 1)$ (left), x (middle) and $1/x$ (right) for a Gamma distribution with shape 0.5 and rate 2, as a function of the Monte Carlo sample size.

We have already used Monte Carlo methods to compute posterior quantities of interest in conjugate models. Outside of models with conjugate priors, the lack of closed-form expression for the posterior precludes inference. Indeed, calculating the posterior probability of

²By contrast, if data are identically distributed but not independent, care is needed

an event, or posterior moments, requires integration of the normalized posterior density and thus knowledge of the marginal likelihood. It is seldom possible to sample independent and identically distributed (iid) samples from the target, especially if the model is high dimensional: rejection sampling and the ratio of uniform method are examples of Monte Carlo methods which can be used to generate iid draws.

Proposition 3.1 (Rejection sampling). *Rejection sampling (also termed accept-reject algorithm) samples from a random vector with density $p(\cdot)$ by drawing candidates from a proposal with density $q(\cdot)$, where $q(\cdot)$ is such that $p(\theta) \leq Cq(\theta)$ for $C \geq 1$ for all values of θ in the support of $p(\cdot)$. A proof can be found in Devroye (1986, Theorem 3.1)*

1. Generate θ^* from the proposal with density q and $U \sim \text{U}(0, 1)$
2. Compute the ratio $R \leftarrow C^{-1}p(\theta^*)/q(\theta^*)$.
3. If $R \leq U$, return θ , else return to step 1.

Rejection sampling requires the proposal q to have a support at least as large as that of p and resemble closely the density. It should be chosen so that the upper bound C is as sharp as possible and close to 1. The dominating density q must have heavier tails than the density of interest. The expected number of simulations needed to accept one proposal is C . Finally, for the method to be useful, we need to be able to simulate easily and cheaply from the proposal. The optimal value of C is $C = \sup_{\theta} p(\theta)/q(\theta)$. This quantity may be obtained by numerical optimization, by finding the mode of the ratio of the log densities if the maximum is not known analytically.

Example 3.2 (Truncated Gaussian distribution). Consider the problem of sampling from a Gaussian distribution $Y \sim \text{No}(\mu, \sigma^2)$ truncated in the interval a, b , which has density

$$f(x; \mu, \sigma, a, b) = \frac{1}{\sigma} \frac{\phi\left(\frac{x-\mu}{\sigma}\right)}{\Phi\{(b-\mu)/\sigma\} - \Phi\{(a-\mu)/\sigma\}}.$$

where $\phi(\cdot)$, $\Phi(\cdot)$ are respectively the density and distribution function of the standard Gaussian distribution.

Since the Gaussian is a location-scale family, we can reduce the problem to sampling X from a standard Gaussian truncated on $\alpha = (a-\mu)/\sigma$ and $\beta = (b-\mu)/\sigma$ and back transform the result as $Y = \mu + \sigma X$.

A crude accept-reject sampling algorithm would consider sampling from the same untruncated distribution with density $g(X) = \sigma^{-1}\phi\{(x-\mu)/\sigma\}$, and the acceptance ratio is

3 Simulation-based inference

$C = \{\Phi(\beta) - \Phi(\alpha)\}$. We thus simply simulate points from the Gaussian and accept any that falls within the bounds.

```
# Standard Gaussian truncated on [0,1]
candidate <- rnorm(1e5)
trunc_samp <- candidate[candidate >= 0 & candidate <= 1]
# Acceptance rate
length(trunc_samp)/1e5
#> [1] 0.342
# Theoretical acceptance rate
pnorm(1)-pnorm(0)
#> [1] 0.341
```

We can of course do better: if we consider a random variable with distribution function F , but truncated over the interval $[a, b]$, then the resulting distribution function is

$$\frac{F(x) - F(a)}{F(b) - F(a)}, \quad a \leq x \leq b,$$

and we can invert this expression to get the quantile function of the truncated variable in terms of the distribution function F and the quantile function F^{-1} of the original untruncated variable.

For the Gaussian, this gives

$$X \sim \Phi^{-1} [\Phi(\alpha) + \{\Phi(\beta) - \Phi(\alpha)\}U]$$

for $U \sim U(0, 1)$. Although the quantile and distribution functions of the Gaussian, `pnorm` and `qnorm` in **R**, are very accurate, this method will fail for rare event simulation because it will return $\Phi(x) = 0$ for $x \leq -39$ and $\Phi(x) = 1$ for $x \geq 8.3$, implying that $a \leq 8.3$ for this approach to work (Botev and L'Écuyer 2017).

Consider the problem of simulating events in the right tail for a standard Gaussian where $a > 0$; Marsaglia's method (Devroye 1986, 381), can be used for that purpose. Write the density of the Gaussian as $f(x) = \exp(-x^2/2)/c_1$, where $c_1 = \int_a^\infty \exp(-z^2/2)dz$, and note that

$$c_1 f(x) \leq \frac{x}{a} \exp\left(-\frac{x^2}{2}\right) = a^{-1} \exp\left(-\frac{a^2}{2}\right) g(x), \quad x \geq a;$$

where $g(x)$ is the density of a Rayleigh variable shifted by a , which has distribution function $G(x) = 1 - \exp\{(a^2 - x^2)/2\}$ for $x \geq a$. We can simulate such a random variate X through the inversion method. The constant $C = \exp(-a^2/2)(c_1 a)^{-1}$ approaches 1 quickly as $a \rightarrow \infty$.

The accept-reject thus proceeds with

1. Generate a shifted Rayleigh above a , $X \leftarrow \{a^2 - 2\log(U)\}^{1/2}$ for $U \sim \text{U}(0, 1)$
2. Accept X if $XV \leq a$, where $V \sim \text{U}(0, 1)$.

Should we wish to obtain samples on $[a, b]$, we could instead propose from a Rayleigh truncated above at b (Botev and L'Écuyer 2017).

```
a <- 8.3
niter <- 1000L
X <- sqrt(a^2 + 2*rexp(niter))
samp <- X[runif(niter)*X <= a]
```

For a given candidate density g which has a heavier tail than the target, we can resort to numerical methods to compute the mode of the ratio f/g and obtain the bound C ; see Albert (2009), Section 5.8 for an insightful example.

Proposition 3.2 (Ratio of uniform method). *The ratio-of-uniform method (Kinderman and Monahan 1977; Wakefield, Gelfand, and Smith 1991) is a variant of accept-reject used to draw samples from a unnormalized density $f(\theta)$ for $\theta \in \Theta \subseteq \mathbb{R}^d$. For some $r \geq 0$, consider the set*

$$C_r = \left\{ (u_0, \dots, u_d) : 0 < u_0 \leq [f(u_1/u_0^r, \dots, u_d/u_0^r)]^{\frac{1}{r+1}} \right\}.$$

If we can generate u_0, \dots, u_d uniformly over C_R , then the draws $(u_1/u_0^r, \dots, u_d/u_0^r)$ are from the normalized density f . Rejection sampling is used to obtain uniform draws over C_r under some conditions on the density and marginal moments. See the `rust` package vignette for technical details and examples. Like with other accept-reject algorithms, the acceptance rate of the proposal goes down with the dimension of the problem.

Example 3.3. The ratio-of-uniform algorithm was used in Example 1.4 to generate draws from the posterior. We illustrate below the `rust` package with a user-specified prior and posterior. We fit a generalized Pareto distribution $Y \sim \text{GP}(\sigma, \xi)$ to exceedances above 10 millions kroner to the danish fire insurance data, using a truncated maximal data information prior $p(\sigma, \xi) \propto \sigma^{-1} \exp(-\xi + 1) \mathbf{I}(\xi > -1)$.

```
data(danish, package = "evir")
# Extract threshold exceedances
exc <- danish[danish > 10] - 10
```

3 Simulation-based inference

```
# Create a function for the log prior
logmdiprior <- function(par, ...){
  if(isTRUE(any(par[1] <= 0, par[2] < -1))){
    return(-Inf)
  }
  -log(par[1]) - par[2]
}
# Same for log likelihood, assuming independent data
loglik_gp <- function(par, data = exc, ...){
  if(isTRUE(any(par[1] <= 0, par[2] < -1))){
    return(-Inf)
  }
  sum(mev::dgp(x = data, scale = par[1], shape = par[2], log = TRUE))
}
logpost <- function(par, ...){
  logmdiprior(par) + loglik_gp(par)
}
# Sampler using ratio-of-uniform method
ru_output <- rust::ru(
  logf = logpost, # log posterior function
  n = 10000, # number of posterior draws
  d = 2, # dimension of the parameter vector
  init = mev::fit.gpd(danish, thresh = 10)$par,
  lower = c(0, -1))
## Acceptance rate
# ru_output$pa
## Posterior samples
postsamp <- ru_output$sim_vals
```

Even without modification, the acceptance rate is 52%, which is quite efficient in the context. The generalized Pareto approximation suggests a very heavy tail: values of $\xi \geq 1$ correspond to distributions with infinite first moment, and those with $\xi \geq 1/2$ to infinite variance.

3.2 Markov chain Monte Carlo

Plain ordinary Monte Carlo is great, but few algorithms are generic enough to be useful in complex high-dimensional problems. Instead, we will construct a Markov chain with a given invariant distribution corresponding to the posterior. Markov chain Monte Carlo methods

Figure 3.2: Scatterplot of posterior samples from the generalized Pareto model applied to Danish fire insurance losses above 10 millions kroner, with maximal data information prior (left) and posterior predictive density on log scale (right).

generate correlated draws that will target the posterior under suitable conditions.³

Before going forward with algorithms for sampling, we introduce some terminology that should be familiar to people with a background in time series analysis.

Definition 3.1 (Stationarity and Markov property). A stochastic (i.e., random) process is (weakly) stationary if the distribution of $\{X_1, \dots, X_t\}$ is the same as that of $\{X_{n+1}, \dots, X_{t+n}\}$ for any value of n and given t .

It is Markov if it satisfies the Markov property: given the current state of the chain, the future only depends on the current state and not on the past.

Example 3.4. Consider a first-order autoregressive process, or AR(1), of the form

³While we won't focus on the fine prints of the contract, there are conditions for validity and these matter!

3 Simulation-based inference

$$Y_t = \mu + \phi(Y_{t-1} - \mu) + \varepsilon_t,$$

where ϕ is the autoregressive process, μ the global mean and ε_t is an iid innovation with mean zero and variance σ^2 . If $|\phi| < 1$, the process is stationary, and the variance does not increase with t . If innovations are Gaussian, then we have $Y_t \mid Y_{t-1} = y_{t-1} \sim \text{No}\{\mu(1 - \phi) + \phi y_{t-1}, \sigma^2\}$

The AR(1) stationarity process Y_t , marginally, has mean μ and unconditional variance $\sigma^2/(1 - \phi^2)$. The AR(1) process is first-order Markov since the conditional distribution $p(Y_t \mid Y_{t-1}, \dots, Y_{t-p})$ equals $p(Y_t \mid Y_{t-1})$.

Autoregressive processes are not the only ones we can consider, although their simplicity lends itself to analytic calculations. More generally, for a correlated sequence, the variance of the stationary distribution is

$$\text{Va}(Y_t) + 2 \sum_{k=1}^{\infty} \text{Co}(Y_t, Y_{t-k})$$

Proposition 3.3. *Intuitively, a sample of correlated observations carries less information than an independent sample of draws. If we want to compute sample averages $\bar{Y}_T = (Y_1 + \dots + Y_T)/T$, the variance will be*

$$\text{Va}(\bar{Y}_T) = \frac{1}{T} \sum_{t=1}^T \text{Va}(Y_t) + \frac{2}{T} \sum_{t=1}^{T-1} \sum_{s=t+1}^T \text{Co}(Y_t, Y_s).$$

In the independent case, the covariance is zero so we get the sum of variances. If the process is stationary, the covariances at lag k are the same regardless of the time index and the variance is some constant, say σ^2 ; this allows us to simplify calculations,

$$\text{Va}(\bar{Y}_T) = \sigma^2 \left\{ 1 + \frac{2}{T} \sum_{t=1}^{T-1} (T-t) \text{Cor}(Y_{T-t}, Y_T) \right\}.$$

Denote the lag- k autocorrelation $\text{Cor}(Y_t, Y_{t+k})$ by γ_k . Under technical conditions⁴, a central limit theorem applies and we get an asymptotic variance for the mean of

$$\lim_{T \rightarrow \infty} T \text{Va}(\bar{Y}_T) = \sigma^2 \left\{ 1 + 2 \sum_{t=1}^{\infty} \gamma_t \right\}.$$

This statement holds only if we start with draws from the stationary distribution, otherwise bets are off.

⁴Geometric ergodicity and existence of moments, among other things.

A visual diagnostic of the time dependence of a Markov chain is the correlogram, which shows the empirical lag- k autocorrelation estimates against lag.

Example 3.5. The lag- k correlation of the stationary autoregressive process of order 1 is ϕ^k , so summing the series gives an asymptotic variance of $\sigma^2(1 + \phi)/(1 - \phi)$. We can contrast that to the variance of the stationary distribution for an independent sample, which is $\sigma^2/(1 - \phi^2)$. The price to pay for having correlated samples is inefficiency: the higher the autocorrelation, the larger the variability of our mean estimators.

Figure 3.3: Scaled asymptotic variance of the sample mean for a stationary autoregressive first-order process with unit variance (dashed) and a corresponding sample of independent observations with the same marginal variance (full line). The plot on the right gives the variance ratio for positive correlations.

We can see from Figure 3.3 that, when the autocorrelation is positive (as will be the cause in all applications of interest), we will suffer from variance inflation. To get the same uncertainty estimates for the mean with an AR(1) process with $\phi \approx 0.75$ than with an iid sample, we would need nine times as many observations: this is the prize to pay.

When can we use output from a Markov chain in place of independent Monte Carlo draws? The assumptions laid out in the ergodic theorem are that the chain is irreducible and acyclic, ensuring that the chain has a unique stationary distribution.

3 Simulation-based inference

To make sense of these concepts, we consider a discrete Markov chain over the integers 1, 2, 3. A discrete-time stochastic process is a random sequences whose elements are part of some set, the state space, here the integers. We can encode the probability of moving from one state to the next via a transition matrix, whose rows contain the probabilities of moving from one state to the next and thus sum to one. We can run a Markov chain by sampling an initial state X_0 at random from $\{1, \dots, 5\}$ and then consider the transitions from the conditional distribution, sampling $p(X_t | X_{t-1})$. Because of the Markov property, the history of the chain does not matter: we only need to read the value $i = X_{t-1}$ of the state and pick the i th row of P_3 to know the probability of the different moves from the current state.

Irreducible means that the chain can move from anywhere to anywhere, so it doesn't get stuck in part of the space forever. A transition matrix such as P_1 below describes a reducible Markov chain, because once you get into state 2 or 3, you won't escape. With reducible chains, the stationary distribution need not be unique, and so the target would depend on the starting values.

Cyclical chains loop around and visit periodically a state: P_2 is an instance of transition matrix describing a chain that cycles from 1 to 3, 3 to 2 and 2 to 1 every three iteration. An acyclic chain is needed for convergence of marginals.

$$P_1 = \begin{pmatrix} 0.5 & 0.3 & 0.2 \\ 0 & 0.4 & 0.6 \\ 0 & 0.5 & 0.5 \end{pmatrix}, \quad P_2 = \begin{pmatrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{pmatrix}.$$

If a chain is irreducible and aperiodic, it has a unique stationary distribution and the limiting distribution of the Markov chain will converge there. For example, we consider a transition P_3 on $1, \dots, 5$ defined as

$$P_3 = \begin{pmatrix} \frac{2}{3} & \frac{1}{3} & 0 & 0 & 0 \\ \frac{1}{6} & \frac{2}{3} & \frac{1}{6} & 0 & 0 \\ 0 & \frac{1}{6} & \frac{2}{3} & \frac{1}{6} & 0 \\ 0 & 0 & \frac{1}{6} & \frac{2}{3} & \frac{1}{6} \\ 0 & 0 & 0 & \frac{1}{3} & \frac{2}{3} \end{pmatrix}$$

The stationary distribution is the value of the row vector \mathbf{p} , such that $\mathbf{p} = \mathbf{p}\mathbf{P}$ for transition matrix \mathbf{P} : we get $\mathbf{p}_1 = (0, 5/11, 6/11)$ for P_1 , $(1/3, 1/3, 1/3)$ for P_2 and $(1, 2, 2, 2, 1)/8$ for P_3 .

Figure 3.4 shows the path of the walk and the empirical proportion of the time spent in each state, as time progress. Since the Markov chain has a unique stationary distribution, we expect these to converge to it.

3.3 Markov chain Monte Carlo algorithms

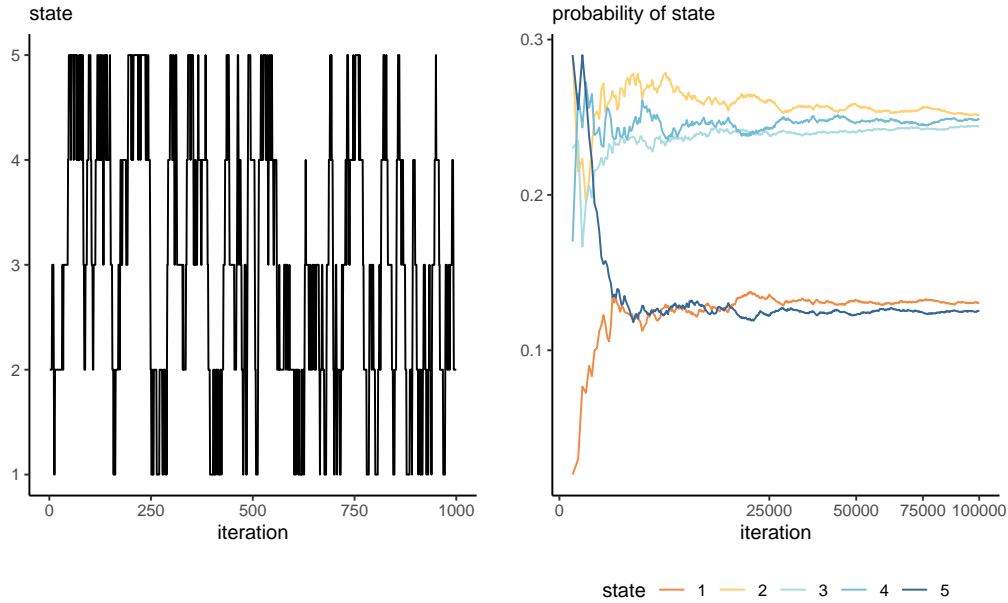

Figure 3.4: Discrete Markov chain on integers from 1 to 5, with transition matrix P_3 , with traceplot of 1000 first iterations (left) and running mean plots of sample proportion of each state visited per 100 iterations (right).

3.3 Markov chain Monte Carlo algorithms

The Markov chain Monte Carlo revolution in the 1990s made Bayesian inference mainstream by allowing inference for models when only approximations were permitted, and coincided with a time at which computers became more widely available. The idea is to draw correlated samples from a posterior via Markov chains, constructed to have the posterior as invariant stationary distribution.

3.4 Metropolis–Hastings algorithm

Named after Metropolis et al. (1953), Hastings (1970), its relevance took a long time to gain traction in the statistical community. The idea of the Metropolis–Hastings algorithm is to construct a Markov chain targeting a distribution $p(\cdot)$.

Proposition 3.4 (Metropolis–Hastings algorithm). *We consider from a density function $p(\theta)$, known up to a normalizing factor not depending on θ . We use a (conditional) proposal*

3 Simulation-based inference

density $q(\boldsymbol{\theta} \mid \boldsymbol{\theta}^*)$ which has non-zero probability over the support of $p(\cdot)$, as transition kernel to generate proposals.

The Metropolis–Hastings build a Markov chain starting from an initial value $\boldsymbol{\theta}_0$:

1. draw a proposal value $\boldsymbol{\theta}_t^* \sim q(\boldsymbol{\theta} \mid \boldsymbol{\theta}_{t-1})$.
2. Compute the acceptance ratio

$$R = \frac{p(\boldsymbol{\theta}_t^*)}{p(\boldsymbol{\theta}_{t-1})} \frac{q(\boldsymbol{\theta}_{t-1} \mid \boldsymbol{\theta}_t^*)}{q(\boldsymbol{\theta}_t^* \mid \boldsymbol{\theta}_{t-1})} \quad (3.1)$$

3. With probability $\max\{R, 1\}$, accept the proposal and set $\boldsymbol{\theta}_t \leftarrow \boldsymbol{\theta}_t^*$, otherwise set the value to the previous state, $\boldsymbol{\theta}_t \leftarrow \boldsymbol{\theta}_{t-1}$.

Remark (Interpretation of the algorithm). If $R > 1$, the proposal has higher density and we always accept the move. If the ratio is less than one, the proposal is in a lower probability region, we accept the move with probability R and set $\boldsymbol{\theta}_t = \boldsymbol{\theta}_t^*$; if we reject, the Markov chain stays at the current value, which induces autocorrelation. Since the acceptance probability depends only on the density through ratios, we can work with unnormalized density functions and this is what allows us, if our proposal density is the (marginal) posterior of the parameter, to obtain approximate posterior samples without having to compute the marginal likelihood.

Remark (Blank run). To check that the algorithm is well-defined, we can remove the log likelihood component and run the algorithm: if it is correct, the resulting draws should be drawn from the prior (Green 1995).

Remark (Symmetric proposals). Suppose we generate a candidate sample $\boldsymbol{\theta}_t^*$ from a symmetric distribution $q(\cdot \mid \cdot)$ centered at $\boldsymbol{\theta}_{t-1}$, such as the random walk $\boldsymbol{\theta}_t^* = \boldsymbol{\theta}_{t-1} + Z$ where Z has a symmetric distribution. Then, the proposal density ratio cancels so need not be computed in the Metropolis ratio of Equation 3.1.

Remark (Calculations). In practice, we compute the log of the acceptance ratio, $\ln R$, to avoid numerical overflow. If our target is log posterior density, we have

$$\ln \left\{ \frac{p(\boldsymbol{\theta}_t^*)}{p(\boldsymbol{\theta}_{t-1})} \right\} = \ell(\boldsymbol{\theta}_t^*) + \ln p(\boldsymbol{\theta}_t^*) - \ell(\boldsymbol{\theta}_{t-1}) - \ln p(\boldsymbol{\theta}_{t-1})$$

and we proceed likewise for the log of the ratio of transition kernels. We then compare the value of $\ln R$ (if less than zero) to $\log(U)$, where $U \sim \text{U}(0, 1)$. We accept the move if $\ln(R) > \log(U)$ and keep the previous value otherwise.

Example 3.6. Consider again the Upworthy data from Example 2.6. We model the Poisson rates λ_i ($i = 1, 2$), this time with the usual Poisson regression parametrization in terms of log rate for the baseline yes, $\log(\lambda_2) = \beta$, and log odds rates $\kappa = \log(\lambda_1) - \log(\lambda_2)$. Our model is

$$\begin{aligned} Y_i &\sim \text{Po}(n_i \lambda_i), & (i = 1, 2) \\ \lambda_1 &= \exp(\beta \kappa) \\ \lambda_2 &= \exp(\beta) \\ \beta &\sim \text{No}(\log 0.01, 1.5) \\ \kappa &\sim \text{No}(0, 1) \end{aligned}$$

There are two parameters in the model, which can be updated in turn or jointly.

The acceptance rate of the algorithm is 35.1% and the posterior means are $\beta = -4.51$ and $\kappa = 0.07$. The standard errors cannot be calculated from the empirical standard deviations. The output of the `coda` package are based on fitting an autoregressive process to the Markov chain and using the formula to compute the central limit theorem variance. An alternative method recommended by Geyer (2011) and implemented in his **R** package `mcmc`, is to segment the time series into batch, compute the means of each non-overlapping segment and use this standard deviation with suitable rescaling to get the central limit variance for the posterior mean.

Figure 3.5: Traceplots of Markov chain of log rate and log odds rate for the Metropolis–Hastings sampler applied to the Upworthy question data.

Figure 3.6 shows the posterior samples, which are very nearly bivariate Gaussian. The parametrization in terms of log odds ratio induces strong negative dependence, so if we

3 Simulation-based inference

were to sample κ , then β , we would have much larger inefficiency and slower exploration. Instead, the code used a bivariate Gaussian random walk proposal whose covariance matrix was taken as a multiple of the inverse of the negative hessian (equivalently, to the observed information matrix of the log posterior), evaluated at of the maximum a posteriori. This Gaussian approximation is called **Laplace approximation**: it is advisable to reparametrize the model so that the distribution is nearly symmetric, so that the approximation is good. In this example, because of the large sample, the Gaussian approximation implied by Bernstein–von Mises’ theorem is excellent.

Figure 3.6: Scatterplot of posterior draws (left) and marginal density plot of log hazard rate (right).

Proposition 3.5 (Visual diagnostics for Markov chains). *It is useful to inspect visually the Markov chain, as it may indicate several problems. If the chain drifts around without stabilizing around the posterior mode, then we can suspect that it either hasn’t reached its stationary distribution (likely due to poor starting values). In such cases, we need to disregard the dubious draws from the chain by discarding the so-called warm up or **burn in** period. While there are some guarantees of convergence, silly starting values may translate into tens of thousands of iterations lost wandering around. Preliminary optimization and plausible starting values help alleviate these problems. Figure 3.7 shows the effect of bad starting values on a toy problem where convergence to the mode is relatively fast. If the proposal is in a*

3.4 Metropolis–Hastings algorithm

flat region of the space, it can wander around for a very long time before converging to the stationary distribution.

*If we run several chains, as in Figure 3.7, with different starting values, we can monitor convergence by checking whether these chains converge to the same target. A **trace rank** plots, shown on right panel of Figure 3.7, compares the rank of the values of the different chain at a given iteration: with good mixing, the ranks should switch frequently and be distributed uniformly across integers.*

Figure 3.7: Traceplots of three Markov chains for the same target with different initial values for the first 500 iterations (left) and trace rank plot after discarding these (right).

The quality of the mixing of the chain (autocorrelation), depends on the proposal variance, which can obtain by trial and error. Trace plots Figure 3.5 show the values of the chain as a function of iteration number. If our algorithm works well, we expect the proposals to center around the posterior mode and resemble a fat hairy caterpillar. If the variance is too small, the acceptance rate will increase but most steps will be small. If the variance of the proposal is too high, the acceptance rate will decrease (as many proposal moves will have much lower posterior), so the chain will get stuck for long periods of time. This is Goldilock's principle, as illustrated in Figure 3.8.

One way to calibrate is to track the acceptance rate of the proposals: for the three chains in Figure 3.8, these are 0.932, 0.33, 0.12. In one-dimensional toy problems with Gaussian distributions, an acceptance rate of 0.44 is optimal, and this ratio decreases to 0.234 when

3 Simulation-based inference

Figure 3.8: Example of traceplot with proposal variance that is too small (top), adequate (middle) and too large (bottom).

$D \geq 2$ Sherlock (2013). This need not generalize to other settings and depends on the context. Optimal rate for alternative algorithms, such as Metropolis-adjusted Langevin algorithm, are typically higher.

We can tune the variance of the global proposal (Andrieu and Thoms 2008) to improve the mixing of the chains at approximate stationarity. This is done by increasing (decreasing) the variance if the historical acceptance rate is too high (respectively low) during burn-in period, and reinitializing after any change with an acceptance target of 0.44. We stop adapting to ensure convergence to the posterior after a suitable number of initial iterations. Adaptive MCMC methods use an initial warm up period to find good proposals: we can consider a block of length L , compute the acceptance rate, multiply the variance by a scaling factor and run the chain a little longer. We only keep samples obtained after the adaptation phase.

We can also plot the autocorrelation of the entries of the chain as a function of lags, a display known as correlogram in the time series literature but colloquially referred to as autocorrelation function (acf). The higher the autocorrelation, the more variance inflation one has and the longer the number of steps before two draws are treated as independent. Figure 3.9 shows the effect of the proposal variance on the correlation for the three chains. Practitioners designing very inefficient Markov chain Monte Carlo algorithms often thin their series: that is, they keep only every k iteration. This is not recommended practice unless storage is an issue and usually points towards inefficient sampling algorithms.

Figure 3.9: Correlogram for the three Markov chains.

Remark (Independence Metropolis–Hastings). If the proposal density $q(\cdot)$ does not depend on the current state θ_{t-1} , the algorithm is termed *independence*. To maximize acceptance, we could design a candidate distribution whose mode is at the maximum a posteriori value. To efficiently explore the state space, we need to place enough density in all regions, for example by taking a heavy-tailed distributions, so that we explore the full support. Such proposals can be however inefficient and fail when the distribution of interest is multimodal. The independence Metropolis–Hastings algorithm then resembles accept-reject. If the ratio $p(\theta)/q(\theta)$ is bounded above by $C \geq 1$, then we can make comparisons with rejection sampling. Lemma 7.9 of Robert and Casella (2004) shows that the probability of acceptance of a move for the Markov chain is at least $1/C$, which is larger than the accept-reject.

In models with multiple parameter, we can use Metropolis–Hastings algorithm to update every parameter in turn, fixing the value of the others, rather than update them in block. The reason behind this pragmatic choice is that, as for ordinary Monte Carlo sampling, the acceptance rate goes down sharply with the dimension of the vector. Updating parameters one at a time can lead to higher acceptance rates, but slower exploration as a result of the correlation between parameters.

If we can factorize the log posterior, then some updates may not depend on all parameters: in a hierarchical model, hyperpriors parameter only appear through priors, etc. This can reduce computational costs.

3 Simulation-based inference

Proposition 3.6 (Parameter transformation). *If a parameter is bounded in the interval (a, b) , where $-\infty \leq a < b \leq \infty$, we can consider a bijective transformation $\vartheta \equiv t(\theta) : (a, b) \rightarrow \mathbb{R}$ with differentiable inverse. The log density of the transformed variable, assuming it exists, is*

$$f_{\vartheta}(\vartheta) = f_{\theta}\{t^{-1}(\vartheta)\} \left| \frac{d}{d\vartheta} t^{-1}(\vartheta) \right|$$

For example, we can use of the following transformations for finite a, b in the software:

- if $\theta \in (a, \infty)$ (lower bound only), then $\vartheta = \log(\theta - a)$ and $f_{\vartheta}(\vartheta) = f_{\theta}\{\exp(\vartheta) + a\} \cdot \exp(\vartheta)$
- if $\theta \in (-\infty, b)$ (upper bound only), then $\vartheta = \log(b - \theta)$ and $f_{\vartheta}(\vartheta) = f_{\theta}\{b - \exp(\vartheta)\} \cdot \exp(\vartheta)$
- if $\theta \in (a, b)$ (both lower and upper bound), then $\vartheta = \text{logit}\{(\theta - a)/(b - a)\}$ and

$$f_{\vartheta}(\vartheta) = f_{\theta}\{a + (b - a)\text{expit}(\vartheta)\}(b - a) \\ \times \text{expit}(\vartheta)\{1 - \text{expit}(\vartheta)\}$$

To guarantee that our proposals fall in the support of θ , we can thus run a symmetric random walk proposal on the transformed scale by drawing $\vartheta_t^* \sim \vartheta_{t-1} + \tau Z$ where $Z \sim \text{No}(0, 1)$. Due to the transformation, the kernel ratio now contains the Jacobian.

Proposition 3.7 (Truncated proposals). *As an alternative, if we are dealing with parameters that are restricted in $[a, b]$, we can simulate $\theta_t^* \sim \text{TNo}(\vartheta_{t-1}, \tau^2, a, b)$. While the benefit of using the truncated proposal isn't obvious, it becomes more visible when we move to more advanced proposals whose mean and variance depends on the gradient and or the hessian of the underlying unnormalized log posterior, as the mean can be lower than a or larger than b while still giving non-zero acceptance. The `TruncatedNormal` package can be used to efficiently evaluate such instances using results from Botev and L'Écuyer (2017) even when the truncation bounds are far from the mode. the normalizing constant of the truncated Gaussian in the denominator of the density is a function of the location and scale parameters: if these depend on the current value of θ_{t-1} , as is the case for a random walk, we need to keep these terms as part of the Metropolis ratio. The mean and standard deviation of the truncated Gaussian are not equal to the parameters μ (which corresponds to the mode, provided $a < \mu < b$) and σ .*

3.4 Metropolis–Hastings algorithm

Proposition 3.8 (Efficient proposals). *Rather than simply build a random walk, we can exploit the geometry of the posterior using the gradient, via Metropolis-adjusted Langevin algorithm (MALA), or using local quadratic approximations of the target.*

Let $p(\theta)$ denote the conditional (unnormalized) log posterior for a scalar parameter $\theta \in (a, b)$. We considering a Taylor series expansion of $p(\cdot)$ around the current parameter value θ_{t-1} ,

$$p(\theta) \approx p(\theta_{t-1}) + p'(\theta_{t-1})(\theta - \theta_{t-1}) + \frac{1}{2}p''(\theta_{t-1})(\theta - \theta_{t-1})^2$$

plus remainder, which suggests a Gaussian approximation with mean $\mu_{t-1} = \theta_{t-1} - f'(\theta_{t-1})/f''(\theta_{t-1})$ and precision $\tau^{-2} = -f''(\theta_{t-1})$. We can use truncated Gaussian distribution on (a, b) with mean μ and standard deviation τ , denoted $\text{TNo}(\mu, \tau, a, b)$ with corresponding density function $q(\cdot; \mu, \tau, a, b)$. The Metropolis acceptance ratio for a proposal $\theta_t^* \sim \text{TNo}(\mu_{t-1}, \tau_{t-1}, a, b)$ is

$$\alpha = \frac{p(\theta_t^*)}{p(\theta_{t-1})} \frac{q(\theta_{t-1} \mid \mu_t^*, \tau_t^*, a, b)}{q(\theta_t^* \mid \mu_{t-1}, \tau_{t-1}, a, b)}$$

and we set $\theta^{(t+1)} = \theta_t^*$ with probability $\min\{1, \alpha\}$ and $\theta^{(t+1)} = \theta_{t-1}$ otherwise. To evaluate the ratio of truncated Gaussian densities $q(\cdot; \mu, \tau, a, b)$, we need to compute the Taylor approximation from the current parameter value, but also the reverse move from the proposal θ_t^* . Another option is to modify the move dictated by the rescaled gradient by taking instead

$$\mu_{t-1} = \theta_{t-1} - \eta f'(\theta_{t-1})/f''(\theta_{t-1}).$$

The proposal includes an additional tuning parameter, $\eta \leq 1$, whose role is to prevent oscillations of the quadratic approximation, as in a Newton–Raphson algorithm. Relative to a random walk Metropolis–Hastings, the proposal automatically adjusts to the local geometry of the target, which guarantees a higher acceptance rate and lower autocorrelation for the Markov chain despite the higher evaluation costs. The proposal requires that both $f''(\theta_{t-1})$ and $f''(\theta_t^*)$ be negative since the variance is $-1/f''(\theta)$: this shouldn't be problematic in the vicinity of the mode. Otherwise, one could use a global scaling derived from the hessian at the mode.

The simpler Metropolis-adjusted Langevin algorithm is equivalent to using a Gaussian random walk where the proposal has mean $\theta_{t-1} + \mathbf{A}\eta\nabla\ell(\theta_{t-1})$ and variance $\tau^2\mathbf{A}$, for some mass matrix \mathbf{A} and a damping factor η . Taking \mathbf{A} as the identity matrix, which assumes the parameters are isotropic (same variance, uncorrelated) is the default choice although seldom far from optimal.

For MALA to work well, we need both to start near stationarity, to ensure that the gradient is relatively small and to prevent oscillations. One can dampen the size of the step initially if needed to avoid overshooting. The proposal variance, the other tuning parameter, is critical to

3 Simulation-based inference

the success of the algorithm. The usual target for the variance is one that gives an acceptance rate of roughly 0.574. These more efficient methods require additional calculations of the gradient and Hessian, either numerically or analytically. Depending on the situation and the computational costs of such calculations, the additional overhead may not be worth it.

Example 3.7. We revisit the Upworthy data, this time modelling each individual headline as a separate observation. We view $n = \text{nimpression}$ as the sample size of a binomial distribution and nclick as the number of successes. Since the number of trials is large, the sample average $\text{nclick}/\text{nimpression}$, denoted y in the sequel, is approximately Gaussian. We assume that each story has a similar population rate and capture the heterogeneity inherent to each news story by treating each mean as a sample. The variance of the sample average or click rate is proportional to n^{-1} , where n is the number of impressions. To allow for underdispersion or overdispersion, we thus consider a Gaussian likelihood $Y_i \sim \text{No}(\mu, \sigma^2/n_i)$. We perform Bayesian inference for μ, σ after assigning a truncated Gaussian prior for $\mu \sim \text{TNo}(0.01, 0.1^2)$ over $[0, 1]$ and an penalized complexity prior for $\sigma \sim \text{Exp}(0.7)$.

3.4 Metropolis–Hastings algorithm

MALA requires critically a good mass matrix, especially if the gradient is very large at the starting values (often the case when the starting value is far from the mode). Given the precision of the original observations, we did not need to modify anything to deal with the parameter constraints $0 \leq \mu \leq 1$ and $\sigma > 0$, outside of encoding them in the log posterior function.

The posterior mean for the standard deviation is 0.64, which suggests overdispersion.
